Proteasomes that mediate the energy-dependent degradation of proteins are composed of 20S core particles (CP) that associate with ATPases of the AAA+ (triple-A or ATPases associated with various cellular activities) superfamily (Figure 7). The CPs are formed by the stacking of four heptameric rings of related α - and β -type subunits into a cylindrical complex of 28 subunits in an $\alpha_7\beta_7\beta_7\alpha_7$ configuration that is approximately 15 nm in length and 11 nm in width. The outermost rings are of α -type subunits and the innermost rings are of β -subunits. In eukaryotes, seven different α - and β -type proteins form the CP, while in prokaryotes, only one to two different α - and β -type proteins are needed. Narrow, gated openings on each end of the cylinder provide portals for substrate entry into the central channel of the CP that harbors two antechambers and one central proteolytic chamber. The two antechambers are formed at the α - and β -ring interfaces and provide a site of initial substrate entry to the central chamber formed by the two β -rings that harbor the proteolytic active sites. The ends of the CP cylinder are in contact with hexameric rings of the AAA+ ATPases. The AAA+ ATPases select, unwind and translocate protein substrates into the chambered interior of the proteolytic nanomachine. Proteasomal CPs and AAA+ ATPase subtypes of distinct biological function and different subunit composition based on cell conditions are identified.

Once protein substrates access the central chamber of the proteasome, hydrolysis of their peptide bonds occurs through nucleophilic attack mediated by N-terminal threonine residues of the CP β -type subunits. These active site threonine residues are exposed by autohydrolysis and removal of the N-terminal propeptides from the β -type proteins during CP assembly. The high concentration of active sites within the CP (up to 14 active sites) facilitates the processive cleavage of substrate proteins into peptide fragments of 3–24 amino acids in length.

A number of AAA+ (triple-A) ATPases are identified that associate with CPs and serve as unfoldases or segregases to facilitate the degradation of proteins by proteasomes. For example, the 26S proteasomes of eukaryotes are formed by association of CPs with 19S regulatory particles or caps that are composed of 18–20 subunits including six regulatory particle triple-A (Rpt1–6) subunits. Rpt1–6 form the hexameric ATPase rings of the 19S cap that are in close contact with the ends of the CP cylinder and important for energy-dependent proteolysis of ubiquitylated proteins. Rpt subunit homologs are also identified in archaea named proteasome-activating nucleotidases or PANs that associate with and stimulate the energy-dependent degradation of structured proteins by CPs. Substrate binding to archaeal PANs activates ATP hydrolysis, which successively promotes substrate unfolding and opening of the

Figure 7 Proteasomes are composed of 20S core particles (CP) and regulatory ATPases of the AAA+ (triple-A or ATPases associated with various cellular activities) superfamily. The CPs are nanocompartmentalized with their proteolytic active sites sequestered on the interior of a cylindrical barrel-shaped complex. The AAA+ ATPase rings facilitate the energy-dependent selection, unwinding and translocation of protein substrates into the chambered interior of the CP for degradation.

CP gates. PAN also facilitates substrate translocation into the central proteolytic chamber of the CP. Cdc48 (p97) is another example of an AAA+ATPase that facilitates energy-dependent movement of protein substrates to proteasomes for hydrolysis in eukaryotes and archaea. Cdc48 complexes can also segregate ubiquitylated substrates from unmodified partners, an activity crucial for certain proteasome-mediated degradation pathways. Mpa and ARC are closely related AAA+ATPases of mycobacteria and actinobacteria that also associate with CPs and facilitate protein degradation.

We now understand that mechanisms, such as ubiquitylation, that are used to generate isopeptide linkages for targeting proteins for destruction by proteasomes are not restricted to eukaryotes. Prokaryotes form ubiquitin-like isopeptide bonds on target lysine residues of proteins by at least two distinct mechanisms that are reversible and regulated. In actinobacteria, the small, disordered Pup (prokaryotic ubiquitin-like protein) is known to be deamidated at its C-terminal Gln and isopeptide linked to proteins by enzymes (Dop and PafA) related to carboxylase-amine ligases. In archaea, the ubiquitin-fold SAMPs (small archaeal modifier proteins) are isopeptide-linked to target lysines by an E1-type mechanism that appears similar in chemistry, but streamlined, compared to E1-E2-E3 enzymes of ubiquitylation. SAMPs are members of a small group of Ub-fold proteins that function not only in protein modification but also in sulfur-transfer pathways associated with tRNA thiolation and molybdopterin biosynthesis. These multifunctional Ub-fold proteins are thought to be some of the most ancient of Ub-like protein modifiers.

Structures as Contributors to Cell Mobility

Magnetosomes

Magnetosomes are specific prokaryotic organelles, which serve as navigational devices in magnetotactic bacteria (MTB) and consist of membrane-enclosed intracellular crystals of a magnetic iron mineral. The chain-like arrangement of magnetosomes confers a magnetic dipole moment to the cell, which enables it to orient and migrate along geomagnetic field lines, a behaviour known as 'magnetotaxis.' Magnetotaxis, in combination with chemotaxis, aerotaxis, and even phototaxis, is thought to assist the cell in finding and maintaining an optimum position within vertical chemical gradients in stratified aquatic environments, such as freshwater and marine sediments.

MTB represent a heterogeneous group of motile aquatic prokaryotes with a variety of morphological types (Figure 8(a)–8(f)), and magnetosome formation occurs in several distinct phylogenetic lineages of Gram-negative bacteria, including representatives from the Alphaproteobacteria, Deltaproteobacteria, Gammaproteobacteria, and the *Nitrospirae* phylum. Some MTB have unusual morphologies, as for example the giant rods with more than 1000 magnetosome particles as well as multicellular magnetotactic forms. Most MTB are recalcitrant to axenic cultivation and only very few species have been isolated in pure culture. All magnetosome particles consist of inorganic ferrimagnetic crystals of either monocrystalline magnetite (Fe_3O_4) or the iron sulfide greigite (Fe_3S_4), which typically fall within the stable single magnetic domain range between 30 and 120 nm. Magnetosome crystals display a variety of uniform species-specific morphologies, which are mostly unknown from inorganic systems (Figure 8(g)–8(m)).

Crystals of the magnetic mineral magnetite are synthesized by a highly controlled biomineralization process within the magnetosome membrane (MM) vesicles, which are formed by invaginations from the cytoplasmic membrane. In all MTB analyzed so far the MM is a phospholipid bilayer associated with proteins. In *Magnetospirillum gryphiswaldense* and related MTB approximately 30 specific polypeptides were identified in the MM, which were designated as Mam (magnetosome membrane), Mms (magnetic particle membrane-specific), and Mtx (magnetotaxis) proteins. Most of these proteins are encoded by several operons within a genomic magnetosome island (MAI) of 100–130 kb, which is conserved between several MTB, and which may have been acquired by horizontal gene transfer. Cloning and transfer of all of the about 30 relevant genes was shown to confer the ability of magnetosome biosynthesis to foreign, hitherto non-magnetic bacteria.

Although the functions of individual magnetosome-associated proteins have not been fully revealed yet, some of them could be assigned specific roles in iron uptake, control over nucleation and growth of crystals. Other proteins assembly, positioning and partitioning of magnetosome chains. For example, Two other proteins, MamJ and MamK, are involved in the assembly, intracellular positioning and partitioning of the highly ordered magnetosome chain, which has an immanent tendency to collapse without some form of support. For example, the deletion of MamJ resulted in cells, which do no longer assembly chains of magnetosomes, but instead magnetosome particles are arranged within clusters. It is thought that MamJ attaches the magnetosome particles in a 'beads-on-a-string'-like configuration to a unique cytoskeletal structure, the magnetosome filament, which is formed by the actin-like MamK protein (Figure 9).

Magnetosomes produced by MTB represent magnetic nanoparticles with unique crystalline, magnetic, and chemical characteristics, which might be useful in a number of various biotechnological applications. Size and morphology of magnetosome crystals are under genetic control, which can be modified by genetic engineering yielding magnetic nano-crystals with 'tailored' characteristics. The encapsulation of the magnetic crystal within the MM provides a natural coating, which can be addressed for modification and functionalization of the particles, for instance for the magnetosome-specific display of biomolecules such as fluorochromes, enzymes and antibodies coupled to the MM.

Gas Vesicles

Gas vesicles are gas-filled protein structures found in many bacteria (mainly phototrophs but also heterotrophs) and Archaea (halophiles and one methanogen). They affect the buoyancy and allow the cells to maintain a position in the water column where

the conditions are optimal for growth. Gas vesicles are recognized as white, light-reflecting particles within the cells by phase-contrast microscopy, and single particles are visualized by electron microscopy (Figure 10(a)). These structures irreversibly collapse when higher pressure is imposed on the cells. Isolated gas vesicles are spindle- or cylinder-shaped structures consisting of 4.6 nm ribs running perpendicular to the long axis of the vesicle (Figure 10(b)). Gas vesicles of haloarchaea are larger in width (diameters of 200–250 nm) compared to gas vesicles of bacteria (33–75 nm), but the maximal lengths are very similar (up to 1 μ m). The reason for the larger diameter in haloarchaea is that these organisms possess a negligible turgor pressure because they accumulate K^+ in a molar range to maintain an iso-osmotic equilibrium with the environment.

Detailed investigations on gas vesicle structure, formation, and also on the genetic regulation have been performed with cyanobacteria and haloarchaea. Gas vesicles develop from hollow bicones that grow in length through the assembly of a cylindrical midsection. Their wall is solely composed of protein; neither lipids nor carbohydrates are found. The major constituent is the 7–8 kDa GvpA, one of the most hydrophobic proteins known. Hydrophobic interactions are responsible for the extremely tight contacts of GvpA proteins that aggregate to form a helical structure of low pitch seen as 4.6 nm ribs. Atomic force microscopy indicates regularly spaced subunits along the ribs that slope in an angle of 54° to the rib axis. The resulting gas vesicle wall is extremely resistant to solubilization by detergents. Gases like O_2 , N_2 , H_2 , or CO_2 freely diffuse inside and are in equilibrium with

those in the cytoplasm; no storage of gas occurs. Water molecules are presumably able to enter the gas vesicle, but the surface tension at the hydrophobic inner surface excludes the formation of liquid water. A second protein, GvpC, attaches at the outside surface and strengthens the gas vesicle structure. The sequence of the 30–40 kDa GvpC exhibits several 33-amino acid repeats (4–5 in cyanobacteria and 6–7 in haloarchaea). It has been proposed that each 33-amino acid repeat spans a rib formed by GvpA, enabling GvpC to clamp adjacent ribs and strengthen the gas vesicle wall.

Genetic analyses indicate that additional Gvp proteins are involved in gas vesicle formation. In haloarchaea 12–14 *gvp* genes are present and up to 10 in cyanobacteria. The *gvp* genes of *Halobacterium salinarum* and *Haloferax mediterranei* are arranged as two oppositely oriented clusters, *gvpACNO* and *gvpDEFGHIJKLM*. Mutation analyses using the gas-vesicle-negative species *Haloferax volcanii* as host reveal that a deletion of *gvpC*, *-D*, *-E*, *-H*, *-I*, or *-N* still yields gas-vesiculated transformants. Gas vesicles formed in the absence of GvpC, GvpI, or GvpH have altered morphologies, whereas the deletion of *gvpN* results in very small bicone structures. GvpE and GvpD are involved in the regulation of *gvp* gene expression, with GvpE acting as a transcriptional activator and GvpD having a repressing function. The remaining eight Gvp proteins are essential and could be minor gas vesicle structural components or take part in their assembly as chaperones.

Gas vesicles are formed only under certain environmental conditions. In cyanobacteria, darkness stimulates whereas UV light appears to repress gas vesicle formation. In haloarchaea, gas vesicle formation is strongly reduced when cells are grown in media with salt concentrations below 17%, or under anaerobiosis. How these environmental factors are signaled and influence *gvp* gene expression still needs to be explored. Transcription of the *gvp* gene cluster is 7- to 10-fold reduced under these conditions, leading to the lack of the accessory proteins GvpF through GvpO.

Structures as Metabolic Reserves

Polyphosphate Granules (Acidocalcisomes)

Polyphosphate (polyP) granules or acidocalcisomes are membrane-bounded organelles that are conserved from bacteria to higher organisms and whose main function is the accumulation of polyP and cations.

The granules were first described in bacteria in 1895 and initially referred to as metachromatic or volutin granules. The names derived from their property to stain red when bacteria were treated with toluidine blue, and for their presence in the bacterium *Spirillum volutans*, respectively. Subsequent investigations found volutin granules in algae, yeasts, and eukaryotic parasites. Eventually they were named polyP granules when this polymer, a linear chain of inorganic phosphates linked by high-energy phosphoanhydride bonds, was found to be present in high concentrations. More recently, based on newly discovered properties, the granules of eukaryotic parasites were named acidocalcisomes. Acidocalcisomes were found to possess a limiting membrane and have also been found in green algae, slime molds, eggs from different species, human platelets (dense granules), and mast cells (mast cell granules). The discovery that acidocalcisomes were membrane-bounded organelles led to the investigation of the presence of a limiting membrane in polyP granules of bacteria. Two bacteria, *Agrobacterium tumefaciens* and *Rhodospirillum rubrum*, have been found to possess membrane-bounded acidocalcisomes. Evidence has also been presented for the presence of these organelles in Archaea.

Acidocalcisomes are spherical, from 15 to about 200 nm in diameter, and sometimes located at one pole of the bacteria. They appear empty when observed by conventional electron microscopy or as electron-dense granules when observed by direct transmission electron microscopy. In addition to polyP, they accumulate a variety of cations, for example, calcium, magnesium, sodium, and zinc. They can also accumulate heavy metal cations from the environment, thus having a detoxifying role. Acidocalcisomes stain well with 4'-6'-diamino-2-phenylindole (DAPI), which stains polyP, as well as with acidotropic fluorescent dyes. A proton pump, a vacuolar H^+ -pyrophosphatase (V- H^+ -PPase), has been detected in the membrane lining the organelle from *A. tumefaciens* and *R. rubrum* (Figure 11).

In bacteria the mobilization of polyP is mainly due to the action of membrane-bound enzymes that catalyze the synthesis and degradation of this polymer, the polyP kinases (PPKs) and the exopolyphosphatases (PPXs), respectively. Two PPKs, PPK1 and PPK2, are present in different bacteria and catalyze the transfer of phosphate residues from ATP to polyP, while the PPXs split phosphate from the end of long-chain polyP in a processive manner.

The functions of acidocalcisomes are those of their main constituents, cations and phosphorus compounds, in particular polyP. PolyP has several functions in bacteria. In addition to its role as phosphorus store, energy source to replace ATP, and cation sequestration and storage, polyP is also important for cell membrane formation and function, transcriptional control, regulation of enzyme activities, response to stress and stationary phase, and to maintain the structural integrity of channels and pumps. By manipulating the expression of the genes involved in polyP metabolism and the cellular levels of their products, different investigators have created phenotypes that provided clues to the role of polyP in the physiology and development of bacteria. Mutant *Escherichia coli* lacking polyP kinase were deficient in polyP; failed to survive the stationary phase; were less resistant to heat, oxidants, and osmotic challenge; and were deficient in adaptation to nutritional deprivation. Disruption of the polyP kinase gene in other bacteria reduced their motility, their ability to develop biofilms, and decreased their virulence in animal models. PolyP levels have also been reduced by overexpression of PPX in *E. coli*, leading to decreased resistance to H_2O_2 . PolyP has an important function as a primordial chaperone in bacteria. It has been established that polyP stabilizes proteins *in vivo*, diminishes the need of bacteria for other chaperone systems to survive proteotoxic stress conditions, and protects a wide variety of proteins against stress-induced unfolding and aggregation. These results help explaining the long known but largely unexplained role of polyP in protecting bacteria against stress conditions.

Methods as described in Seufferheld M, Lea C, Vieira M, et al. (2004) The H^+ -pyrophosphatase of *Rhodospirillum rubrum* is predominately located in polyphosphate-rich acidocalcisomes. *Journal Biological Chemistry* 279: 51193–51202. Bar = 0.5 μ m.

Sulfur Globules

Sulfur can accumulate in the form of water-insoluble globules as a transient or the final product during the oxidation of reduced sulfur compounds (sulfide, polysulfides, thiosulfate, polythionates, and elemental sulfur) by either chemotrophic or phototrophic sulfur-oxidizing bacteria. While sulfur is deposited extracellularly by part of these organisms, others form sulfur globules within the confines of the cell wall (Table 1), i.e. sulfur is present as a bacterial inclusion *sensu strictu*. Internal sulfur globules are easily recognized even via light microscopy as they are highly light refractive, up to 2 μm in diameter and can comprise 20–34% of the of the cell dry mass. Cultures of cells containing sulfur globules exhibit a characteristic milky appearance.

Those organisms forming intracellular sulfur globules for which the systematic affiliation has been unequivocally determined belong to the α -, β -, γ - and ϵ - Proteobacteria (Table 1). They include the anoxygenic phototrophic purple sulfur bacteria of the family Chromatiaceae as well as *Thiomargarita namibiensis* and the filamentous sulfur-oxidizing bacteria of the genera *Beggiatoa* and *Thioploca*, some of the largest and most conspicuous bacteria in nature. In thin-section electron micrographs, sulfur deposits appear as conspicuous, empty and electron-lucent space. The exact intracellular localization of sulfur globules has not been resolved in all cases. Often, sulfur inclusions appear to be separated from the cytoplasm by a unit membrane which may be continuous with the cytoplasmic membrane depending on the organism. Topologically, these sulfur globules are periplasmic.

In many cases, sulfur inclusions have been observed to be bounded by a protein envelope which usually consists of a 2–5 nm single layer. Pentalaminal envelopes of 12–14 nm thickness have also been described. The envelopes are fragile in fixatives used for transmission electron microscopy therefore, their lack in electron micrographs is not a valid proof for their absence *in vivo*. Analysis of the sulfur globule proteome in the purple sulfur bacterium *Allochrochromatium vinosum* revealed that the envelope consists of four different, extremely hydrophobic proteins (SgpA, SgpB, SgpC, SgpD) of 8.5–20.8 kDa. Relative transcript abundances for all four of these genes strongly increase upon exposure of the cells to sulfide, thiosulfate and elemental sulfur compared to photoorganoheterotrophic growth on malate in the absence of reduced sulfur compounds. All four proteins are synthesized with cleavable N-terminal signal peptides mediating Sec-dependent transport into the periplasm. *A. vinosum* mutants lacking SgpB and SgpC are no longer able to oxidize sulfide and to form sulfur inclusions from it. SgpC is important for expansion of the globules and is less abundant than the other three proteins. All sulfur globule proteins share highly repetitive amino acid sequences rich in regularly spaced proline residues and the prediction to be structural proteins. SgpD appears to be a coiled-coil protein. In general, these proteins are characterized by superhelical twisting of two or more alpha helices around one another. They can form rod-like tertiary structures and include the intermediate filaments of the metazoan cytoskeleton as well as bacteria specific cytoskeletal proteins.

X-ray absorption near edge structure spectroscopy of intact cells revealed at least three main different forms of sulfur in bacterial sulfur globules reflecting the different ecological and physiological types of sulfur bacteria: polythionates in the extracellular sulfur formed by *Acidithiobacillus*, cyclo-octasulfur (S_8) in *Thiomargarita* and *Beggiatoa*, and long sulfur chains probably terminated by organic residues (monoorganyl/bisorganyl polysulfanes) in phototrophic sulfur bacteria.

Sulfur deposition is comparatively well characterized in the purple sulfur bacterium *A. vinosum*. In this organism, the oxidation of sulfide is catalyzed in the periplasm by flavocytochrome *c* and two different sulfide:quinone oxidoreductases (SqrD and SqrF). Polysulfides are the first readily detectable product of this step. It is unknown how polysulfides are converted into sulfur globules. When thiosulfate is oxidized, only its sulfane group is stored as sulfur; the sulfone sulfur is immediately excreted as sulfate. Thiosulfate oxidation is catalyzed by the periplasmic Sox proteins (SoxXAK, SoxXYZ, SoxB, SoxL). Proteins related to most of these are

Table 1 Occurrence and properties of bacterial sulfur inclusions

Organism/group	Main substrates for sulfur globules	Properties of sulfur globules
α-Proteobacteria		
Magnetotactic bacteria	H_2S	Intracellular
β-Proteobacteria

part of the widely distributed Sox multienzyme system that oxidizes thiosulfate directly to sulfate. The intermediate formation of sulfur globules in organisms like *A. vinosum* is probably related to the lack of SoxCD, a protein proposed to oxidize SoxY-bound sulfane sulfur. In its absence, the latter may instead be transferred to growing sulfur globules. A complicated mechanism that requires the presence of many different enzymes encoded in the *dsr* (dissimilatory sulfite reductase) gene cluster, is necessary for oxidation of stored sulfur. Low molecular weight organic persulfides like glutathione amide persulfide probably serve as carrier molecules transferring sulfur from the periplasmic sulfur globules into the cytoplasm. Here, a sulfur relay system sets in that transfers sulfur atoms via a sulfur mobilizing rhodanese, to the proteins TusA and DsrEFH and finally to DsrC, which then serves as the direct substrate for reverse acting sulfite reductase, DsrAB. The product of this step is sulfite which is finally oxidized to sulfate either directly via the membrane-bound iron-sulfur molybdoenzyme SoeABC or by an indirect pathway involving formation of adenosine-5'-phosphosulfate (APS) catalyzed by APS reductase and ATP sulfurylase. Under anoxic conditions sulfur globules can also serve as an electron acceptor reserve that allows a rudimentary anaerobic respiration leading to production of sulfide. The underlying enzymatic mechanisms are unresolved.

Glycogen Reserves

The occurrence of glycogen-like reserves has been reported in over 50 different bacterial species. These inclusions may be naked or membrane-enclosed. Naked inclusions are 20–100 nm in diameter. In *Clostridium pasteurianum*, membrane-enclosed polyglucose inclusions are found to be 160–300 nm in diameter.

Three reactions are involved in the synthesis of bacterial α -glucan inclusion bodies. First is the synthesis of the glycosyl donor adenosine diphosphate-glucose (ADP-Glc) that is catalyzed by ADP-glucose pyrophosphorylase (ADP-Glc PPase; EC 2.7.7.27). ADP-Glc is then utilized for synthesis of a new α -1,4-glucosidic bond in the glycogen molecule and this reaction is catalyzed by glycogen synthase (EC 2.4.1.21). After extensive elongation of the α -1,4-glucosidic chain, branching enzyme (EC 2.4.1.18) then catalyzes formation of the α -1,6-linked branch chains.

The synthesis of ADP-Glc is the first committed step in bacterial glycogen synthesis and the enzymatic step is allosterically activated by glycolytic intermediates. The nature of the activator is dependent on the major carbon assimilatory pathway dominant in the organism. For example, enteric bacteria that utilize glycolysis for glucose assimilation have fructose-1, 6-bisphosphate as an activator for its ADP-Glc PPase while the cyanobacteria being oxygenic photosynthesizers have 3-phosphoglycerate (3-PGA) as the enzyme activator. The allosteric inhibitors for the ADP-Glc PPases are AMP, or P_i or ADP, indicating that ADP-Glc and glycogen synthesis are also controlled by the energy status of the cell. The regulatory properties of ADP-Glc PPase, together with the fact that ATP is one of the substrates of the enzyme, indicates that storage polysaccharides in bacteria are maximal when cellular carbon and energy are in excess.

Strong experimental evidence supports the view that ADP-Glc PPase is a regulatory enzyme in the bacterial glycogen synthetic pathway. In *E. coli* and *Salmonella typhimurium*, mutants have been isolated that were affected in their ability to accumulate glycogen, and their ADP-Glc PPases display altered regulatory properties. Also, in the unicellular green alga *Chlamydomonas reinhardtii* ADP-Glc PPase is activated by 3-PGA and its inhibitor is P_i . Starch-deficient mutants were isolated and were shown to have ADP-Glc PPases that could not be activated by 3-PGA. Regulation of ADP-Glc synthesis in bacteria therefore agrees with the generalization that a biosynthetic pathway is effectively regulated at its first unique step. The enzymatic and structural properties of the glycogen biosynthetic enzymes have been extensively reviewed and the regulatory properties of the various bacterial ADP-Glc pyrophosphorylases discussed and compared.

An alternative pathway to glycogen synthesis has recently been demonstrated in mycobacteria and is known as the GlgE pathway and involves the α -1,1 diglucoside trehalose (α -D-glucopyranosyl- (1 $\rightarrow$ 1)- α -D-glucanopyranoside). Trehalose is converted by the enzyme TreS to the α -1,4 disaccharide, maltose which is then converted by Pep2 (maltokinase) with ATP to maltose 1-phosphate. The maltose-1-P can then be transferred the maltosyl residue to the end of exterior chains of the glycogen molecule by GlgE. The GlgE enzyme is thus a maltosyl transferase. In summary,

1. Trehalose $\rightarrow$ Maltose (TreS; trehalase synthase)
2. Maltose + ATP $\rightarrow$ Maltose-1-P + ADP (Pep2; maltose kinase)
3. Maltose-1-P $\rightarrow$ Maltosyl- α -1,4 Glycogen + P_i (GMPMT; glycogen, maltose-1-P maltosyl transferase)

Genetic regulation of glycogen synthesis in *E. coli* K12 and in *S. typhimurium* has been studied. The structural genes for glycogen biosynthesis are clustered in two adjacent operons and contain genes for glycogen catabolism. They are located approximately 75 min on the *E. coli* K12 chromosome, and the gene order at this location is *glgP*–*glgA*–*glgC*–*glgX*–*glgB*–*asd*. *glgA* encodes glycogen synthase, *glgC*, the ADP-Glc PPase, and *glgB*, the glycogen-branching enzyme. *glgX* encodes an isoamylase and *glgP*, glycogen phosphorylase.

Glycogen biosynthesis is under the direct control of at least three global regulatory systems: catabolite repression (stimulation of *glgABC* expression by cAMP), stringent response (stimulation of *glgABC* expression by pGpp), and repression of the *glgABC* expression by the *csrA* gene product, a 61-amino acid polypeptide. Transcription of *glgCA* appears to involve initiation events at four or more separate sites upstream from the genes and the *glgC* and *glgA* gene products; ADP-Glc pyrophosphorylase and glycogen synthase are in higher relative concentration in stationary phase versus exponential phase.

Mutations leading to higher levels of the biosynthetic enzymes also result in enhanced accumulation of specific transcripts.

The *csrA* gene maps to 58 min on the *E. coli* chromosome and its gene product negatively modulates posttranscriptionally by facilitating decay of *glgCA* mRNAs. The *csrA* gene product is a specific mRNA-binding protein binding to *csrB* RNA. Binding of the

csrA gene product to *csrB* RNA inhibits the repression of the *glgCA* operon and the *glgB* genes. Since *csrB* RNA increases in stationary phase, it is believed that the binding of *csrA* gene product relieves repression of the glycogen biosynthetic genes by the *csrB* RNA.

Polyhydroxyalkanoate Granules

Cytoplasmic granules consisting of PHAs have been described in a wide, taxonomically diverse range of prokaryotes and are probably the most frequent storage compounds for carbon and energy in bacteria making up to 90% of the cell dry weight (Figure 12). Poly(3-hydroxybutyrate) (PHB) is the most common PHA, and their granules and biosynthesis have been studied in most detail.

Approximately 150 other hydroxyalkanoates and also mercaptoalkanoates have been identified as constituents of these polyesters beside 3-hydroxybutyrate. The constituents are distinguished with regard to length and structure of the alkyl side chain or the position of the hydroxyl group. Bacteria accumulate PHAs when a carbon source is provided in excess or under nutrient or oxygen limitation when supply of carbon is still adequate. PHAs are of interest for several technical applications because they represent thermoplasts and elastomers that are in contrast to most biodegradable, compostable, and resorbable synthetic polymers. Therefore, several attempts were made by the chemical industry to produce various PHAs on a large scale.

The first step in PHB biosynthesis is the condensation of two acetyl-CoA molecules to acetoacetyl-CoA by β -ketothiolase (PhaA). Acetoacetyl-CoA is reduced to *R*-(–)-3-hydroxybutyryl-CoA by acetoacetyl-CoA reductase (PhaB), which is then converted into PHB by PHA synthase (PhaC). In *Ralstonia eutropha* and many other bacteria the genes for these enzymes constitute the *phaCAB* operon. Several other pathways have been described for biosynthesis of various PHAs. Unspecific PHA synthases are the key enzymes of PHA biosynthesis. They polymerize a large variety of different hydroxyalkanoates if the respective hydroxyacyl-CoA thioester is available. *R. eutropha* produces, for example, also the copolymer poly(3-hydroxybutyrate-co-3-hydroxyvalerate), which was commercialized for use as a biodegradable packaging material. This bacterium is also capable to synthesize copolyesters containing 4-hydroxybutyrate (4HB) or poly(4HB) homopolyesters, which are of interest for applications in medicine and pharmacy. Pseudomonads synthesize PHAs consisting of 3-hydroxyalkanoic acids of medium carbon-chain length like 3-hydroxyoctanoate or 3-hydroxydecanoate. Biosynthesis of these PHAs depends either on fatty acid *de novo* biosynthesis plus an acyltransferase (*atf*)-transferring the hydroxyacyl moiety from the acyl carrier protein to coenzyme A if they are synthesized from glucose or other carbohydrates, or on fatty acid β -oxidation if they are synthesized from fatty acids, oils, or even hydrocarbons.

A thin layer consisting of regularly arranged small, amphiphilic proteins called phasins (PhaP) and eventually also phospholipids surrounds PHA granules. Granule formation is initiated in the cytoplasm when soluble PHA synthase starts synthesis and remains covalently linked to the growing polyester chain (Figure 13). Micelles of amphiphilic enzyme-PHB complexes with the enzyme at the surface and the hydrophobic polymer in the core are formed. When the micelles enlarge, only a minor fraction of the hydrophobic surface remains covered by PhaC, which remains attached to the surface. Phasin PhaP1, whose formation can be induced in *R. eutropha*, mostly covers the surface. Mutants lacking PhaP1 contain only one, large PHB granule because the granules

Figure 13 Model proposed for poly(3-hydroxybutyrate) (PHB) granule formation in bacteria. Phasins are amphiphilic proteins. This figure is based on studies done in *Ralstonia eutropha*. Reproduced from Wältermann M, Hinz A, Robenek H, et al. (2005) Mechanism of lipid-body formation in prokaryotes: How bacteria fatten up. *Molecular Microbiology* 55: 750–763, with permission from Blackwell. For further information see this reference.

coalesce during enlargement. In *R. eutropha* there are three PhaP1 homologues expressed, which might play a role together with PHA depolymerases for intracellular degradation of PHB. The transcriptional repressor PhaR strictly controls the expression of PhaP1.

Fusions of the phasin protein to other proteins were also detected at the surface of PHA granules in the cells. Phasins on the other side bind also to lipid granules. When PhaP1 and C-terminal fusions of PhaP1 with enhanced green fluorescent protein (eGFP) or with *E. coli* β -galactosidase (LacZ) were separately expressed in the triacylglycerol (TAG)-accumulating actinomycetes *Rhodococcus opacus* PD630, and *Mycobacterium smegmatis* mc²155 (see below), PhaP1 became associated with the TAG inclusions and was mainly located on the surface. This provides various possibilities to generate functionalized granules or nanoparticles for various applications.

Triacylglycerol and Wax Ester Granules

TAG, that is, trioxoesters of glycerol and long-chain fatty acids, and wax esters (WE), that is, oxoesters of an alcohol and a fatty acid both of long carbon-chain length, that occur as insoluble cytoplasmic inclusions serve less frequently than PHAs as carbon and

Figure 14 (a) Structural formulas of triacylglycerol (TAG) and wax ester (WE). (b) Transmission electron micrograph of a cell of the Gram-positive bacterium *Rhodococcus opacus* strain PD630 showing TAG granules. Cells were grown in a mineral salts medium containing 1.5% (wt. vol⁻¹) sodium gluconate and had accumulated various TAGs to about 80% of the cell dry matter. Reproduced from Alvarez HM, Mayer F, Fabritius D, and Steinbüchel A (1996) Formation of intracytoplasmic lipid inclusions by *Rhodococcus opacus* strain PD630. *Archives of Microbiology* 165: 377–386, with permission from Springer Science and Business Media.

energy storage compounds in bacteria (Figure 14(a)). Whereas the chemical structure of TAGs is similar to those accumulated in most plant and animal cells, the chemical structure of WEs of most bacteria is similar to those produced by jojoba and the sperm whale (*Physeter macrocephalus*). The latter consists mainly of in total 32–36 carbon atoms, with saturated and monoenoic C16 and C18 fatty acid and fatty alcohol residues. Similar to the accumulation of PHAs, TAG and WE accumulation occur during growth limitation due to a lack of a suitable nitrogen source and imbalanced growth.

TAGs as the main storage lipid in bacteria have mainly been described in Actinomycetales like *Actinomyces* sp., *Arthrobacter* sp., *Mycobacterium* sp. including *Mycobacterium tuberculosis*, *Nocardia* sp., *Rhodococcus* sp., *Gordonia* sp., and *Dietzia* sp., and in streptomycetes such as *S. coelicolor*, *S. lividans*, and *Micromonospora echinospora*. Species of the Gram-negative genera *Acinetobacter* and *Alcanivorax* also frequently accumulate TAGs. These species accumulate only minor amounts of TAGs besides major amounts of WEs, which serve as the predominant storage lipid. In addition to these bacteria, WEs were also described to occur in members of the genera *Corynebacterium*, *Micrococcus*, *Moraxella*, *Mycobacterium*, and *Nocardia*. WEs do not occur exclusively as intracellular storage compounds, since some strains of *Acinetobacter* sp., for example, *A. borkumensis* and *A. jadensis*, and several other marine bacteria were also reported to synthesize extracellular WEs from hydrocarbons or to secrete lipids from the cells into the environment. However, the origin and possible function of these extracellular WEs remain to be elucidated. So far, TAGs and WEs have never been reported to occur in Archaea.

In *R. opacus* strain PD630, one of the best-studied model organisms with respect to its neutral lipid metabolism, TAGs can amount up to 80% of the cell dry matter (Figure 14(b)). In *Acinetobacter baylyi* strain ADP1, a novel type of a promiscuous enzyme, the wax ester/acyl-CoA:diacylglycerol acyltransferase (WE/DGAT), shortly referred also to as *atf*, catalyses the final step in TAG and also in WE biosyntheses. It can therefore be considered as the key enzyme for the biosynthesis of these lipids. Mutants with a defective *atf* gene are mostly or even completely impaired in WE and TAG biosyntheses. This enzyme is unique to bacteria, and it does not occur in eukaryotes. It synthesizes a wide range of different lipids. Interestingly, all bacteria capable of synthesizing these storage compounds among those whose genomes have been sequenced contain at least one or even several genes coding for homologues of this *atf*. The genome of *M. tuberculosis* contains 15 genes coding for *atf* homologues. Therefore, in bacteria, it is likely that TAGs and WEs are generally synthesized by this type of enzyme.

Although WE and in particular TAG inclusions are in most cases indistinguishable from PHA granules by microscopic techniques, significant differences from the latter with regard to surface structure and biogenesis were found. Lipid biosynthesis starts at the cytoplasmic membrane to which the *atf*s are attached (Figure 15). At the very beginning small lipid droplets (SLD) are formed, which remain bound to the membrane-associated *atf*. They form a thin lipid layer at the inner leaflet of the cytoplasmic membrane. The SLDs increase in size and conglomerate subsequently to lipid prebodies that still remain associated with the membrane. They are released only in a later stage into the cytoplasm where they mature due to further coalescence of the SLDs inside the prebodies. Conclusive evidence exists that these lipid inclusions are surrounded by a phospholipid monolayer and that proteins homologous to phasins are absent.

It was recently shown that the mammalian lipid body proteins, perilipin A, adipose differentiation-related protein (ADRP), and tail-interacting protein of 47 kDa (TIP47), which comprise the so-called PAT family of proteins, are targeted to prokaryotic TAG bodies *in vivo* as revealed by analysis of fusions of these proteins to eGFP and by immunocytochemical labeling of ultrathin cryosections and freeze-fracture replicas. In contrast, the maize (*Zea mays* L.) oleosin could not be directed to the surface of lipid inclusions when heterologously expressed in the recombinant actinomycetes *R. opacus* PD630 and *M. smegmatis* mc²155.

Figure 15 Model proposed for triacylglycerol (TAG) and wax ester (WE) granule formation in prokaryotes. WS/DGAT is wax ester/acyl-CoA:diacylglycerol acyltransferase. (2005) Mechanism of lipid-body formation in prokaryotes: How bacteria fatten up. *Molecular Microbiology* 55: 750–763, with permission from Blackwell.

Cyanophycin Granules

Cyanophycin is the third known polymer, the others being polyglutamate and polylysine, consisting of a restricted number of amino acids, that is synthesized by a nonribosomal synthetase. Cyanophycin is a comb-like polymer with α -amino- α -carboxy-linked L-aspartate residues representing the poly(aspartate) backbone and with L-arginine residues linked to the β -carboxylic groups of aspartate (Figure 16(a)). It is also referred to as cyanophycin grana protein (CGP) or multi-L-arginyl-poly-L-aspartate in the literature. Lysine and some other amino acids, for example, ornithine or citrulline, may in some bacteria partially replace arginine in the cyanophycin synthesized in the cytoplasm or during *in vitro* biosynthesis of cyanophycin using the purified enzyme. It is found in the cytoplasm as insoluble membrane-less inclusions (Figure 16(b)). Bacteria accumulate cyanophycin as storage compound for nitrogen, carbon, and energy when growth is limited by another nutrient.

Cyanophycin is synthesized by many cyanobacteria and also several nonphotosynthetic bacteria like *Acinetobacter calcoaceticus* independently of ribosomal protein biosynthesis. The key enzyme of cyanophycin synthesis is cyanophycin synthetase encoded by *cphA*. The enzyme catalyses the consecutive addition of aspartate and arginine residues to a primer or to the growing polymer chain and requires one ATP for addition of each constituent. In addition, the enzyme is dependent on the presence of K^+ , Mg^{2+} , a (cyanophycin) primer, and a thiol reagent such as β -mercaptoethanol in the reaction mixture. Cyanophycin is intracellularly degraded by cyanophycinases encoded by *cphB* if growth resumes yielding β -Asp-Arg dipeptides that are hydrolysed by a peptidase to the monomers. Cyanophycin is extracellularly also degraded by cyanophycinases secreted into the medium by some bacteria. Proteases seem generally not to be capable of hydrolyzing cyanophycin.

So far technical applications are not known for cyanophycin. However, due to the availability of cyanophycin synthetase genes from several cyanobacteria and the occurrence of cyanophycin also in heterotrophic bacteria that grow much faster and to many higher cell densities than cyanobacteria, cyanophycin has become much more readily available. It is foreseen that the material properties and applications will now be intensively investigated. However, cultivation of heterotrophic bacteria for production of large amounts of cyanophycin in the cells seems to be a burden for the organism due to the competition of the ribosomal protein biosynthesis machinery and the cyanophycin synthetases for the amino acids aspartate and arginine. This can be overcome by using amino acid rich complex media or by directly feeding both amino acids. However, this increases the production process costs. A further alternative is to use an addition system. A recombinant strain of *R. eutropha* has been recently constructed for the

Figure 16 (a) Structural formula of cyanophycin. (b) Transmission electron micrograph of cells of the Gram-negative bacterium *Acinetobacter baylyi* showing cyanophycin granules. Cells were grown in a mineral salts medium containing 75 mmol l^{-1} arginine and 10 mmol l^{-1} ammonium sulfate and had accumulated cyanophycin up to about 40% of the cell dry matter. Bar = $1 \mu\text{m}$. Micrograph courtesy of Yasser Elbahloul and Rudolf Reichelt, Westfälische Wilhelms-Universität Münster, with permission from Shively, 2006a and Shively, 2006b Bacterial inclusions. production of cyanophycin with a defective chromosomal KDPG aldolase gene (*eda*), which is essential for growth of the cells if, for example, fructose is used as carbon source. Instead, the strain contained a plasmid containing not only a cyanophycin synthetase gene (*cphA*) but also an intact *eda* gene. Thereby, *cphA* was coupled to *eda*, and therefore the cells could not lose the plasmid if they grew on fructose.

Inclusions of *Bacillus Thuringiensis*

The insecticidal bacterium, *Bacillus thuringiensis* (Bt) Berliner, consists of approximately 60 subspecies, many that occur commonly in habitats such as soil, leaf litter, plants, insect feces, and the midguts (stomachs) of many insect species. All subspecies of Bt are characterized by the production of one or more crystalline parasporal inclusions during sporulation, each of which typically contains one or more insecticidal proteins (Figure 17). At the end of sporulation, the host cell lyses, releasing the spore and parasporal inclusions. Many of the parasporal proteins are highly and selectively insecticidal for certain insect species. These proteins are protoxins activated by proteolytic cleavage in the insect midgut after ingestion. Activation typically requires a highly alkaline pH of 8–11. Once activated, the proteins bind to and destroy midgut cells, paralyzing and killing sensitive insects within 2 days of ingestion. In natural hosts of Bt like the larvae of certain moths that attack grains, mosquito larvae, and larvae of certain beetles, the spores germinate in the midgut as the larvae become intoxicated. Subsequently, vegetative Bt cells invade the moribund and dead larvae, colonize these, and sporulate. A typical increase in Bt cells in natural hosts ranges from 300- to 3000-fold. Without the insecticidal proteins, spores are poor insect pathogens and rarely kill insects. Thus, the role of these proteins is to intoxicate and contribute to the death of natural hosts, thereby providing a rich source of nutrients for reproduction of Bt.

The insecticidal proteins produced by Bt are so effective that several subspecies have been developed as commercial insecticides, some of which have been used for decades. In addition, through genetic engineering, important crop plants in the United States and several other countries such as Australia, China, and India have been developed that produce one or more Bt proteins to control important lepidopteran and beetle pests. Among these pests are corn borers, corn rootworms, and important cotton pests such as the pink bollworm and cotton budworm.

The most widely used Bt is *B. thuringiensis* subsp. *kurstaki*, a subspecies that typically produces four inclusion proteins, Cry1Aa, Cry1Ab, Cry1Ac, and Cry2Aa, packaged into two crystalline parasporal inclusions. The Cry1 proteins cocrystallize forming a bipyramidal crystal, whereas Cry2Aa forms a separate cuboidal crystal (Figure 17). This subspecies is the active ingredient of numerous commercial insecticides used to control lepidopteran pests of field and vegetable crops, and forests.

Figure 17 Sporulated cells of *Bacillus thuringiensis* and parasporal protein crystals. (a) Phase contrast micrograph of cells from a sporulated culture of *B. thuringiensis* just before lysis. Parasporal protein crystals (arrowheads) lie adjacent to oval spores. (b) Scanning electron micrograph of typical Cry1 and Cry2 crystals purified from a sporulated culture of *B. thuringiensis* subsp. *kurstaki*, isolate HD1. The parasporal body of this isolate consists of a bipyramidal crystal that contains Cry1Aa, Cry1Ab, and Cry1Ac, which cocrystallize, and a separate cuboidal crystal composed of Cry2Aa molecules. (c) Carbon replica of a typical bipyramidal Cry1 type protein crystal exhibiting the lattice of Cry1A molecules that compose the crystal. The HD73 isolate of *B. thuringiensis* subsp. *kurstaki* only expresses a single *cry1Ac* gene, and its parasporal body contains only a single crystal, such as this one, which measures approximately 1 mm from point-to-point along the longitudinal axis. (d) Transmission electron micrograph through a parasporal body of the HD1 isolate of *B. thuringiensis* subsp. *kurstaki* illustrating the embedment of the cuboidal Cry2A crystal (P2) in the bipyramidal crystal (P1). Labels in (d) include P1/CryIA, a, b, c, P2, and Cry2Aa. Bar in (d) = 200 nm. Micrograph in (c) by Hannay CL.

Another successful Bt is *B. thuringiensis* subsp. *israelensis*, used to control larvae of many mosquito and blackfly species. This subspecies produces a spherical parasporal inclusion that contains four major proteins, Cry4Aa, Cry4Ba, Cry11Aa, and Cyt1Aa. The Cry proteins are related to those of *B. thuringiensis* subsp. *kurstaki*, but are only active against mosquitoes, blackflies, and related dipterans. Cyt proteins are unrelated to Cry proteins, but synergize some of these. Several commercial products based on this subspecies are used to control both nuisance and vector mosquitoes and blackflies. This subspecies proved particularly important in the World Health Organization's Onchocerciasis Control Program in West Africa, where it was used during the 1980s and 1990s in rotation with chemical insecticides to control larval populations of the blackfly vector, *Simulium damnosum*, of the filarial worm that causes this disease.

A third Bt subspecies that has been developed commercially is *B. thuringiensis* subsp. *morrisoni* (strain tenebrionis), which is used to control beetle pests such as the Colorado potato beetle. The key proteins in this and related strains are known as Cry3 proteins. These are essentially nontoxic to lepidopteran and dipteran pests, but highly effective against many beetle species.

One of the most remarkable features of Bt inclusion proteins is their remarkable safety record, whether used in bacterial insecticides or transgenic crops. Hundreds of millions of people have eaten these proteins over the past 40 years, as they occur commonly on many vegetable crops, and now in many transgenic crops. But not a single human is known to have become ill due to eating these proteins. The reason for this high degree of safety is that these proteins have evolved to only bind to the stomachs of certain types of insects. As recombinant DNA techniques are improved further, it is likely that Bt proteins will be used to protect many other crops from insect damage, including such important crops as rice and soybeans. Since the initial release of so-called Bt cotton in 1996, which produces the Cry1Ac protein to control certain caterpillar pests, several other Cry proteins (Cry1Ab, Cry2, and Cry3B) have been genetically engineered into important commodity crops such as corn and soybeans, to help protect these crops from other caterpillar and beetle pests. These crops, i.e., Bt corn and Bt soybeans, along with the earlier and newer versions of Bt cotton, now make up most of acreage of cotton and corn crops grown in the United States, as well as in several other countries including Argentina, Australia, Brazil, China, and India. In the future, it is likely that genes encoding Cry proteins will be engineered into other crops such as sorghum and even coffee, and possibly even vegetable crops, and will be used virtually worldwide owing to their high degree of efficacy, non-target safety and lack of detrimental environmental effects compared to synthetic chemical insecticides.

Introduction

Definitions

An organism is defined as intracellular where it is entirely enclosed within the cell membrane of the cell of another organism. In other words, the habitat of an Intracellular microorganism is a cell of another organism (Fig. 1(a)). These associations, by definition, comprise organisms of unequal size, and the partners are generally known as the (smaller) symbiont within the (larger) host. The description of the intracellular microorganism as a symbiont derives from the original definition of symbiosis as any persistent association between different species, irrespective of the impact of the association on the fitness of the participating organisms. The specific cells of a multicellular host (e.g., plant or animal) that are colonized by intracellular symbionts are known as host cells.

Impact of Intracellular Symbioses on the Host

In terms of function, intracellular symbionts are diverse and often variable (Fig. 1(b)). Some intracellular symbionts are deleterious to the host. These taxa are commonly described as pathogens or parasites, and include taxa that are obligately intracellular (e.g., *Rickettsia* agents of typhus fever, and the sexually-transmitted *Chlamydia trichomatis*), as well as taxa with a required intracellular stage of their life cycle (e.g., the merozoite stage of the malaria agent *Plasmodium* within erythrocytes of the vertebrate host) or that are facultatively intracellular (e.g., *Salmonella*, *Shigella*). Other intracellular symbionts are beneficial and, in many cases, required by the host. For example, cockroaches are absolutely dependent on their intracellular symbiont *Blattabacterium cuenoti*, and the fungus *Rhizopus microsporus* requires its intracellular symbiont *Paraburkholderia rhizoxinica*, while many leguminous plants have facultative associations with rhizobia (including the genera *Rhizobium*, *Mesorhizobium*, *Sinorhizobium* and *Bradyrhizobium*). The impact of some intracellular symbionts on their host is, however, variable, depending on host genotype or species, physiological condition (especially immunocompetence) and environmental circumstance. For example, *Mycobacterium tuberculosis*, the bacterial agent of tuberculosis in humans, can persist for extended periods in macrophages of the lung without causing any disease symptoms; and the green alga *Chlorella* promotes the survival of its ciliate host *Paramecium bursaria* under a light-dark cycle, but is deleterious to the ciliate host in the dark.

All intracellular symbionts are predicted to impose some cost on their host. This is because all the resources utilized by a symbiont for maintenance and growth are derived, of necessity, from the host cell (Fig. 1(a)). Furthermore, all symbiont waste products, including end-products of metabolism that do not contribute to growth, cell wall fragments etc., are deposited into the host cell, potentially perturbing host cell function. In the many associations that promote host fitness, these costs are outweighed by other beneficial symbiont traits, which may include the consumption of host waste products and the release of metabolites that are utilized by the host (Fig. 1(a)).

Taxonomic Diversity of Intracellular Symbioses

As the preceding section illustrates, intracellular associations are taxonomically diverse. Nevertheless, distinct taxonomic patterns are evident (Table 1). Most conspicuously, nearly all known hosts of intracellular symbionts are eukaryotes, and all phyla of Eukaryotes studied in detail include representatives with intracellular symbionts. The propensity of eukaryotes to engage with intracellular symbionts is reinforced by the overwhelming evidence that the common ancestor of all extant eukaryotes had mitochondria, which are derived from intracellular α -proteobacteria. Interestingly, vertebrate animals are colonized by a diversity of intracellular pathogens, but just one beneficial intracellular symbiont is known, the alga *Oophila* associated with embryos of the salamander *Ambystoma maculatum*. The intracellular partners include many different Bacteria, for example representatives of the phyla Proteobacteria, Firmicutes, Bacteroidetes, Actinobacteria and Cyanobacteria (the latter include the ancestor of plastids in algae and land plants); and multiple eukaryotes, including various protists (e.g., *Toxoplasma*), fungi (e.g., *Cryptococcus*) and algae, notably the dinoflagellate *Symbiodinium* in corals are other marine animals. By comparison, intracellular representatives of the Archaea are dominated by just one functional group, methanogens of the class Methanomicrobia.

Fig. 1 Intracellular microorganisms. (a) The intracellular microorganism is enclosed within a host cell. Many intracellular microorganisms are in the cytosol, often localized to a compartment that is bounded by a membrane of host origin (shown as black circle) and variously known as a vacuole, vesicle or symbiosome. Some intracellular microorganisms are localized to sites other than the cytoplasm, including the nucleus (e.g., *Candidatus Berkella aquae* in freshwater amoebae) and between the two membranes of mitochondria (e.g., the α -proteobacterium *Candidatus Midichloria mitochondrii* in *Ixodes* ticks). Intracellular microorganisms obtain all their requirements from the surrounding host cell, and thereby compete with the host cell, except where the inputs to the microorganism are host waste metabolites. Similarly, waste metabolites and other outputs of an intracellular microorganism may perturb host cell function. An effector is a molecule (usually a protein) of microbial origin that has evolved in the context of the association with the host and functions specifically to perturb host cell function, to the benefit of the microorganism. Many intracellular microorganisms that are beneficial to the host overproduce and release nutrients that contribute to host metabolism and growth. (b) Variation in the impact of intracellular microorganisms on host fitness. Some intracellular microorganisms are invariably either deleterious or beneficial to the host (obligate pathogens and mutualists, respectively), and the impact of other microorganisms on host fitness varies with genotype and environmental factors.

Gaining Access to the Host Cell Habitat

The principal route of access to hosts is by phagocytosis, i.e., the microbial cell is engulfed by a portion of the cell membrane of the host cell. The phagocytosed microorganism is, thus, in the cytoplasm of the host cell but separated from the cytoplasmic contents by a host membrane (Fig. 1(a)).

Some host cells are highly phagocytic, and internalize a wide range of particles; for these systems, microbial access to the host cell appears to involve no specific molecular recognition events between the partners. This applies to phagocytically-active protists and the gut epithelium of various lower invertebrates (e.g., Cnidaria, Turbellaria) that internalize food particles by phagocytosis for intracellular digestion. (In most animals, including mammals, digestion is predominantly extracellular in the gut lumen.) Photosynthetically-active algal symbionts are acquired by this route, for example *Symbiodinium* in scleractinian corals and *Chlorella* in freshwater ciliates and hydra. Internalization by phagocytosis is also observed for macrophages of the animal cellular immune system. For example, several bacterial pathogens, including *Legionella pneumophila*, *Coxiella burnetii* and *Mycobacterium tuberculosis* gain entry to mammalian macrophages by passive phagocytosis. The usual fate of microbial cells internalized by these cells is delivery to the lysosome and digestion for host nutrition or anti-microbial defense, and the mechanisms by which persistent intracellular microorganisms evade this fate are considered in the following section (*Persistence of Intracellular Microorganisms in the Host Cell*).

Other intracellular microorganisms gain entry to eukaryotic cells by inducing engulfment by nonphagocytic cells. This involves microbe-induced perturbation to the membrane and underlying cytoskeleton of the host cell. Research on interactions between bacterial pathogens and mammalian cells has identified two broad mechanisms: trigger and zipper. Many bacterial taxa display either one or the other mode of internalization, for example the trigger reaction by *Shigella* and zippering by *Listeria* and *Yersinia*. Exceptionally, *Salmonella enterica* has the capacity for multiple routes of entry, including both zipper and trigger mechanisms.

The trigger mechanism involves the transfer of bacterial effector proteins into the target host cell, resulting in major reorganization of the cytoskeleton of the host cell. For example, the effector proteins SipA and SipC of *Salmonella enterica* are delivered via a Type-III secretion system (T3SS, encoded by SPI-1) into epithelial cells of the intestine, causing polymerization and reorganization of host cell actin filaments. Together with other cytoskeletal-modifying *Salmonella* proteins (e.g., SopA, SopB, SopD, SopE), these proteins induce membrane ruffles that engulf the bacterial cell by a process most accurately described as macro-pinocytosis.

Table 1 Survey of intracellular microorganisms. This survey is not comprehensive, and includes some widespread and notable examples

Host	Examples of Intracellular Microorganisms			
	Bacteria	Archaea	Protists	Fungi
Eukaryotes				
Protists				
^a Trypanosomes	β -proteobacteria			
Foraminifera			Various dinoflagellates	
Amoebae	Various including <i>Chlamydia</i> , <i>Burkholderia</i> , <i>Legionella</i>		^b <i>Parkinsela</i> (kinetoplastid) in <i>Paramoeba</i>	
Ciliates		Methanogens in various anaerobic ciliates	<i>Chlorella</i> in <i>Paramecium bursaria</i>	
Fungi	Burkholderiaceae in arbuscular mycorrhizal fungi and in <i>Rhizopus microsporus</i>			
Plants				
Legumes	Rhizobia			
<i>Gunnera</i>	Cyanobacteria (Nostocaceae)			
Animals	Various, including <i>Chlamydia</i> , <i>Rickettsia</i> Various chemosynthetic bacteria in molluscs, annelids <i>Wolbachia</i> and bacteriocyte symbionts in insects		Various, e.g., Apicomplexa, trypanosomes, <i>Entamoeba</i> Dinoflagellate algae (<i>Symbiodinium</i>) and <i>Chlorella</i> in sponges, cnidarians, turbellarians and mollusks <i>Oophila</i> in <i>Ambystoma maculatum</i> (salamander)	Microsporidia, <i>Cryptococcus</i> ^d “yeast-like” mycetocyte symbionts in some insects
Bacteria				
^c <i>Tremblaya princeps</i>	Various γ -proteobacteria (e.g., <i>Moranella</i>)			

^aIn many species, e.g., of genus *Crithidia*, but not reported in trypanosome parasites of humans.

^bOnly known intracellular protist within a protest.

^cIntracellular symbionts restricted to specialized cells known as bacteriocytes (housing bacteria) or mycetocytes (housing fungi).

^d*Tremblaya* is an intracellular symbiont in mealybug insects.

In the zipper mechanism, the interaction is between surface proteins of the bacterium and target host cell. Specific outer membrane proteins bind tightly to receptors on the host cell membrane, inducing localized changes in the organization of the membrane and underlying cytoskeleton and internalization. The protein-protein interactions that induce zippering have been characterized in various pathogen-host cell interactions. These include Rck-invasin of *Salmonella* which binds to the host cell epidermal growth factor receptor (EGFR), and two Internalin (Inl) proteins of *Listeria monocytogenes*: InlA which interacts with the host cell adhesion molecule E-cadherin and InlB which binds to the hepatocyte growth factor receptor (Met).

A further example of active invasion of host cells is displayed by apicomplexan parasites, including *Toxoplasma* and *Plasmodium*. Being eukaryotes, the apicomplexans possess an actomyosin cytoskeleton, which has been shown to be crucial for penetration of the host cell. The key structures are the cytoskeleton associated with the inner membrane complex that lies internal to the cell membrane of the apicomplexan cell, together with proteins and other products discharged from specialized secretory organelles known as rhoptries and micronemes at the cell apex. These proteins induce tight adhesion to the host cell membrane and then rapid internalization. For example, *Plasmodium* merozoites can make contact with mammalian erythrocytes, re-orientate for apical contact with the host cell membrane, and invade the host cell within just 2 min.

Large-scale reorganization of host cell membrane and cytoskeleton is also exhibited by the root cells of leguminous plants that come into contact with rhizobia bacteria. The rhizobia are trapped at the tip of a root hair. This interaction induces local invagination of the root hair cell membrane, and then the progressive ingrowth of the membrane, forming an infection thread that penetrates ultimately to the inner cortex of the root. The bacterial and plant determinants of this process have been identified by genetic analysis, and include the sustained release from the rhizobial cells of both an acylated chitin oligomer known as the Nod factor and exopolysaccharide, both with side groups that determine compatibility between specific bacterial strains and host plant species. When the infection thread reaches in the inner cortex, each bacterial cell is internalized into a cell, enclosed within the membrane derived from the infection thread.

The mode of entry of some intracellular microorganisms is unknown. Particularly intriguing is the remarkable intracellular symbiosis within the bacterium *Tremblaya princeps* (Table 1). *Tremblaya* is an intracellular symbiont within cells of mealybugs (insects of the family Coccidae) and different lineages of this bacterium are known to contain one of several γ -proteobacteria. Phylogenetic data suggest that the different γ -proteobacteria do not represent multiple, independent acquisitions but replacements of one taxon by another in certain lineages of *Tremblaya*. Further sampling is required to assess whether *Tremblaya* is particularly susceptible to invasion by γ -proteobacteria (or certain taxa within the γ -proteobacteria), and the molecular basis of this interaction.

Persistence of Intracellular Microorganisms in the Host Cell

At the point of internalization into a host cell, intracellular microorganisms are bounded by a membrane of host cell origin (Fig. 1(a)). The default fate of these membrane-bound structures is fusion with host cell lysosomes, exposing the internalized microbial cells to the very low pH and hydrolases of the lysosomal contents. Some intracellular microorganisms, including the bacteria *Legionella pneumophila* and *Coxiella burnetii*, are remarkably tolerant of the conditions in the phagolysosome. On internalization into the host cell, these bacteria release protein effectors via a type-IV secretion system (T4SS) that delay phagosome-lysosomal fusion until the bacterial cell has made the necessary physiological changes for transition from an extracellular to intra-lysosomal habitat. However, most persistent intracellular microorganisms are not trafficked to the lysosome, and they avoid this fate by various mechanisms, notably by suppressing maturation of the phagosome, such that it fails to fuse with a lysosome, and by escape from the phagosome.

Various approaches have been adopted to investigate the molecular mechanisms by which many intracellular microorganisms evade trafficking to the lysosomes. In particular, the host membrane has been scored for its Rab protein content because these GTP-binding proteins define the developmental stage of vesicles involved in membrane trafficking in eukaryotic cells. For example *Chlamydia trachomatis* is bounded by a Rab6-bearing membrane, while Rab5 is associated with the membrane bounding *Mycobacterium tuberculosis*, Rab7 with *Salmonella enterica* and the homolog of human Rab3C with the alga *Symbiodinium* in the sea anemone *Aiptasia pallida*. Although this approach has diagnostic value for each individual association, there is an increasing appreciation that microbial perturbation of membrane function yields atypical Rab protein patterns, so limiting comparative functional interpretation. Other analyses of the protein and lipid composition of the host membrane bounding various intracellular microorganisms are also indicative of mixed affinities of the membrane. In particular, the vacuole bounding *Legionella pneumophila* fuses with secretory vesicles from the endoplasmic reticulum, a process is driven by bacterial effectors secreted by the T4SS Dot/Icm of *Legionella*, rendering the membrane incapable of fusing with the lysosome; and the symbiosomal membrane bounding rhizobia in cells of the plant root nodule includes proteins that are diagnostic of both the cell membrane and endoplasmic reticulum in uninfected plant cells, as well as various unique proteins.

A minority of recently-internalized microorganisms transfer from the phagosome into the cytosol. Where studied, this process is mediated by microbial proteins. For example, the pathogen *Listeria* secretes a protein toxin, listeriolysin O (LLO) which creates pores in the membrane, permitting the escape of the bacterial cells. Although LLO has broad cytotoxicity, it is rapidly denatured and degraded, so avoiding generalized damage to *Listeria*-infected host cells. Once in the cytosol, some bacteria nucleate the actin, generating actin "comet tails" that power bacterial movement through the cell. These actin structures are produced by the Arp2/3 complex, which is recruited to the bacterial via specific bacterial proteins, e.g., IcsA/VirG of *Shigella*, ActA of *Listeria*.

The long-term persistence of intracellular microorganisms requires the sustained growth and proliferation of the microbial cells within the host cell and spread, either by partitioning with host cell division or (especially for terminally-differentiated host cells in multicellular hosts) by transfer from infected host cells to uninfected cells. Where host cells bear one or small numbers of intracellular microorganisms, e.g., 1–7 *Symbiodinium* cells in gastrodermal cells of corals, host and symbiont division tend to be synchronized and the microbial partner is actively partitioned between host daughter cells, although the mechanisms remain to be identified. Coordinated host-symbiont cell division is unnecessary in host cells with hundreds or thousands of microbial partners (as, for example, for many intracellular symbioses in insects) because the probability that a host daughter cell would be symbiont-free by chance is vanishingly small.

Microbial manipulation of host cell growth and division has been demonstrated, most notably in the apicomplexan *Theileria* which, on taking up a position close to the host cell nucleus, induces high rates of host cell division and coupled proliferation of the parasite. A different strategy for population expansion is adopted by the apicomplexan *Toxoplasma gondii*, which, on depleting the resources in one host cell, spreads via an intermediate extracellular phase to previously-uninfected cells. First, the *Toxoplasma* parasite secretes a perforin-like protein TgPLP1, which permeabilizes the vacuole membrane; and then the cell membrane is ruptured by processes that are not fully understood but appear to involve parasite-mediated activation of host calpain-proteases and consequent perturbation of the host cell cytoskeleton.

Transmission of Intracellular Microorganisms Between Hosts

All living hosts are finite, in both space and time. The long-term persistence of intracellular symbionts depends on their transmission from one host to another. Two broad routes of transmission are available: horizontal and vertical transmission. Vertical transmission comprises transfer from parent host to offspring; in sexually-reproducing hosts with anisogamy (gametes of unequal size), the microorganisms are usually transferred to the larger gamete, e.g., to the oocyte of animals, leading to maternal inheritance. For horizontally-transmitted symbionts, the relatedness of the donor and recipient hosts is not defined, and some horizontally-transmitted microorganisms can have an extended free-living phase in the external environment (e.g., rhizobia in the soil). Vertical transmission has far-reaching evolutionary consequences for the host-microbial relationship. Specifically, the fitness of a vertically-transmitted symbiont is promoted by the vigor and fecundity of its host, and this overlap in selective interest between host and symbiont is particularly strong where horizontal transmission is limited or blocked. Thus, vertical transmission tends to reduce the virulence of microbial partners, and this trait is widespread in hosts that require their microbial partners.

Some horizontally-transmitted intracellular microorganisms have no apparent adaptations that facilitate long-range contact with the host. For example, various pathogens that colonize the gut epithelial cells of humans and other mammals gain entry to the gut lumen in food and water. Similarly, taxa that colonize macrophages and other cells of the mammalian lung are transmitted between hosts via aerosols, especially when the infected host coughs or sneezes with the 'explosive' release of pathogen-bearing droplets. Motile cells of other horizontally-transmitted taxa, however, display chemotaxis towards their host. For example, free-living cells of the dinoflagellate alga *Symbiodinium* swim towards the plume of ammonia emitted from alga-free cnidarian host, *Cassiopea*, and various rhizobia display chemotaxis towards root exudates of host legumes. For *Sinorhizobium meliloti*, which associates with alfalfa roots, nonmotile cells display both elevated minimum inoculum density for nodule formation and time to nodule formation. *mcp* (methyl accepting chemotaxis protein) genes of the bacterial partner play an important role in mediating rapid and effective colonization of the host this trait. For example, *mcpU* in *S. meliloti* promotes chemotaxis towards the amino acid proline, a major component of host plant root exudates.

Vertical transmission in asexually-reproducing protists is mediated by the retention of the intracellular partners through mitosis and cytokinesis of the host cell, and at sexual reproduction through meiosis to the gametes. In animal hosts, intracellular microorganisms that are transferred to the germ line early in animal development are, similarly, partitioned to the gametes and transmitted vertically. For example, *Wolbachia* gains access to the oocytes of its insect hosts by this route. Research on *Drosophila* fruit flies indicates that *Wolbachia* interacts with the products of key genes in insect germ-line stem cell proliferation and differentiation. In particular, *Wolbachia* infection has been implicated in the rapid sequence evolution of the gene *bam* (bag of marbles), and can partially restore fertility in female *D. melanogaster* with *bam* null mutations. Other intracellular symbionts in animals are restricted exclusively to somatic cells, e.g., gastrodermis cells of Cnidaria (corals, hydra etc), and bacteriocytes (whose sole function appears to be the housing and maintenance of the intracellular symbionts) in various insects. Generally, these intracellular microorganisms are eliminated from the somatic cell, and transferred via an extracellular phase to the host oocytes, where they are engulfed by the developing oocyte. For example, *Chlorella* in hydra pass from the gastrodermal layer through the mesoglea to the developing oocytes in the ectoderm of the hydra body column, and the bacterial symbionts are expelled from the stomach disc of reproductive female anopluran lice and transit through the insect body cavity to the ovaries, although their mode of locomotion of the bacterial cells has not been established.

Patterns of transmission observed over short timescales, especially in laboratory conditions, can give an incomplete picture of the diversity of transmission modes available to some intracellular microorganisms. For example, the horizontal transmission of some *Symbiodinium* is likely facilitated by passage through the gut of mobile coral-feeding fish, such that viable *Symbiodinium* cells are distributed across the reef via fecal pellets. In addition, some intracellular symbionts display vertical transmission with higher

fidelity in benign laboratory conditions than in the field (*Hamiltonella* in aphids is a likely example). The occasional horizontal transmission of intracellular bacteria between taxonomically-divergent hosts can be evident as incongruence between the phylogeny of the host and symbiont. This is evident, for example, for both *Wolbachia* and *Hamiltonella* in insects.

Nutrient Exchange Between Intracellular Microorganisms and Their Hosts

As Fig. 1(a) illustrates, intracellular microorganisms derive their entire nutritional requirement from the surrounding host cell. Energy acquisition is a key requirement for intracellular symbionts. The dominant energy source for many taxa is host-derived sugars, especially glucose, but other sources include pyruvate utilized by *Shigella*, glycerol by *Listeria* and dicarboxylic acids utilized by rhizobia. The obligate intracellular parasite *Rickettsia prowazekii* obtains host ATP in exchange for bacterial ADP via an ADP/ATP translocase, Tlc1; this bacterium has additional *tlc* genes, whose protein products mediate the uptake of other nucleotides. Host-derived fatty acids and lipids are also utilized by various intracellular microorganisms, as a source of energy; long-chain and unsaturated fatty acids are also essential nutrients for some intracellular microorganisms.

An indication that intracellular microorganisms have access to a diversity of host metabolites is that they are generally auxotrophic for many nutrients, including the fatty acids mentioned in the previous paragraph as well as amino acids, nucleotides and often cofactors. The evidence comes from genome annotations and, for cultivable microorganisms, analyzes of the growth requirements in culture. Bacterial amino acid auxotrophy can compete particularly acutely with host requirements in animals and various protists that are also auxotrophic for a subset of amino acids (particularly the 9–10 essential amino acids that contribute to protein but cannot be synthesized *de novo* by animals). For example, various intracellular parasites require multiple amino acids that are either essential or of high value to the host, e.g., the 7 amino acids required by *Legionella* include 5 animal-essentials (leucine, isoleucine, valine, methionine and threonine) as well as arginine, synthesized by mammals at low rates, and the sulfur-amino acid cysteine. In contrast, beneficial intracellular microorganisms tend to be auxotrophic for amino acids that are synthesized by the host. This is illustrated by *Buchnera aphidicola*, whose genetic capacity for amino acid synthesis almost perfectly complements that of its aphid host: *Buchnera* produces the 10 essentials and just two of the non-essentials produced by the host, glycine and the sulfur-amino acid, cysteine.

For various systems, the microbial transporters that mediate uptake of host-derived nutrients have been characterized. However, inferences from genome data for some intracellular bacteria, e.g., *Buchnera* lead to many predicted metabolic inputs without annotated transporters for their acquisition. Multiple processes may contribute to resolution of this inconsistency: errors in gene annotation (especially in relation to transporters), host-to-microbe transfer via membrane vesicles, and non-specific permeability of the microbial cell membrane. Cysteine-rich peptides of host origin enhance the permeability of rhizobia (as well as promoting terminal differentiation of these bacterial cells), and similar peptides are expressed in the cells bearing intracellular bacteria of some insects.

The host membrane that separates many intracellular microorganisms from the surrounding host cell contents can represent a major barrier to nutrient acquisition by the microbial cells. For legume-rhizobia associations, the symbiosomal membrane substantially restricts rhizobial access to sugar pools in the host cell cytoplasm and regulates the supply of dicarboxylates to the rhizobial cells. In some associations, the microbial partner can modify the transport capabilities of the bounding membrane. The acquisition of arginine by *Mycobacterium* and *Salmonella* is mediated by the recruitment of the host cationic amino acid transporter SLC7A1 to the vacuole membrane; and the vacuole membrane bounding *Toxoplasma* has enhanced permeability, permitting the nonspecific leakage of many cytosolic metabolites to the parasite. However, *Toxoplasma* do not have free access to all nutrients. In particular, host cell mitochondria accumulate around the parasite and oxidize fatty acids at high rates, thereby restricting parasite access to these host nutrients.

Intracellular microorganisms release various metabolites into the host cell. These include the waste products of metabolism and, in some microorganisms, the products of metabolic pathways that are both absent from the host and advantageous to the host. For example, rhizobia release ammonium, the product of nitrogen fixation, *Chlorella* algae release the sugar maltose, and *Buchnera* releases essential amino acids. In other systems, the identity of the released products is uncertain or variable (e.g., glucose, fatty acids and glycerol have all been implicated as release products of *Symbiodinium*, and the compounds released from chemoautotrophic bacteria in various invertebrates are not characterized with confidence). Various mechanisms have been implicated in the selective release of metabolites from intracellular microorganisms. Maltose release from symbiotic *Chlorella* is induced by low pH (conditions that pertain within the symbiosome membrane) and the intracellular pool of maltose is very small or undetectable under all conditions, suggesting that the proton gradient may trigger the synthesis and release of this compound. Ammonium release from rhizobia is facilitated by an ammonium transporter that is localized to the symbiosome membrane and closely associated with a cytosolic host glutamine synthetase, resulting in the efficient assimilation of symbiont-derived ammonium into glutamine and maintenance of a steep ammonium concentration gradient from symbiont to surrounding host cell cytoplasm (Fig. 2(a)). The synthesis and release of the essential amino acid methionine by *Buchnera* is driven by supply of the host-derived substrate cystathionine (Fig. 2(b)), raising the possibility that essential amino acid production in this bacterium may generally be regulated by substrate supply; however, the molecular and metabolic basis of this putative process remains to be established.

Fig. 2 Metabolic processes that promote nutrient overproduction by intracellular microorganisms. The intracellular microorganism (blue circle) bounded by a membrane of host origin (black circle) within the host cell (black rectangle) with metabolic reactions (solid lines) and transport reactions (dashed lines) shown. (a) Intracellular rhizobium (including the genera *Rhizobium*, *Sinorhizobium*, *Bradyrhizobium*) in infected cell (host cell) of the root nodule of leguminous plants. Release of ammonia (comprising NH_3 and NH_4^+), the product of nitrogen fixation, is maintained by the high concentration gradient of ammonia across the rhizobium-host cell interface, maintained by: first, association of host glutamine synthetase with the ammonium transporter on the symbiosome membrane (shown), resulting in the efficient assimilation of ammonia into glutamine in the host cell cytoplasm; and, second, repression of rhizobium glutamine synthetase, the major route of ammonia assimilation in the rhizobia (not shown). (b) Intracellular *Buchnera* in bacteriocyte (host cell) of an aphid. Overproduction of the essential amino acid methionine is driven by substrate supply, specifically the concentration of cystathionine in the bacteriocyte. *Note*: a single intracellular microorganism is shown (the infected cell of legumes and bacteriocyte of aphids contain large numbers of rhizobia and *Buchnera* cell, respectively).

Genome-Scale Consequences of Intracellular Symbiosis

The genome of many intracellular microorganisms is much-reduced, in comparison to related taxa, with some genomes less than 1 Mb (Fig. 3). This condition is not unique to intracellular microorganisms (for example, the genome of the extracellular bacterium *Stammera* in midgut ceca of the tortoise beetle *Cassida* is just 0.27 Mb). There is wide agreement that genome reduction in these various microorganisms is driven by relaxed selection on genes not required in the host habitat and accumulation of deleterious mutations by drift in microorganisms with very small effective population size. Once genes involved in DNA repair and recombination start to decay, genetic degradation and gene loss can accelerate, leading to large genome deletions and very rapid genome reduction in some lineages.

Genome reduction in some intracellular microorganisms has been accompanied, and possibly promoted, by compensatory changes in the host genome and the acquisition of helper microorganisms. For example, the loss of the gene *ilvE* coding the terminal transaminase reaction in branched chain amino acid synthesis in *Buchnera* is compensated by the selective expression of an aphid gene *BCAT*, which can mediate the same reaction, in the host cell containing *Buchnera* (Fig. 4(a)). In this way, the synthesis of branched chain amino acids in the aphid-*Buchnera* symbiosis is shared between the two partners. Some shared essential amino acid synthesis pathways involve genes acquired horizontally by the insect genome from bacteria (e.g., *argGH* from bacteria of the order Enterobacteriales in the whitefly *Bemisia tabaci*) (Fig. 4(b)). In other instances, multiple bacterial taxa contribute to essential amino acid synthesis, either mediating the production of different essential amino acids (e.g., *Sulcia* and

Fig. 3 The genomes of intracellular bacteria. (M): intracellular mutualist; (FP): facultative parasite; (OP) obligate parasite * *Wolbachia pipientis* is a reproductive parasite that induces cytoplasmic incompatibility, parthenogenesis and male killing in various insects and other arthropod hosts, but it can also enhance host fitness, especially by conferring protection against virus infections. ** The large genome size of *Sinorhizobium meliloti* and other rhizobia can be linked to its lifestyle as both a mutualist of legumes and saprophyte in soils; other intracellular mutualists included in this figure are unknown or rare in the external environment. Data collated from NCBI Genomes database on 9 May 2018.

Fig. 4 Coevolved metabolic pathways between intracellular bacteria and their host. Host reactions compensate for gene loss from intracellular bacteria subject to genomic decay. (a) Synthesis of isoleucine in the aphid-*Buchnera* association involves two aphid enzymes: cystathionine- γ -lyase (CGL) and branched chain amino acid aminotransferases (BCAT). (b) Synthesis of arginine in the whitefly-*Portiera* association involves two enzymes of bacterial origin, argininosuccinate synthetase (ArgG) and argininosuccinate lyase (ArgH), transferred horizontally from Enterobacteriaceae to the whitefly genome (these genes are not derived from the intracellular symbiont *Portiera*, which is a member of the Halomonadaceae).

Hodgkinia in cicadas) or different reactions in the synthesis of an individual amino acid (e.g., *Tremblaya* and *Moranella* in mealybugs). Generally, the intermediate metabolites are transferred between the different host and microbial compartments mediating the various metabolic reactions, but the mechanisms underlying metabolite transfer and multi-partner coordination of metabolic function are not known.

Glossary

Bacterioferritin (BFR) A subclass of prokaryotic ferritin that contains heme.

Ferritin (FTN) A large intracellular iron storage protein, present in both prokaryotic and eukaryotic cells.

Haptoglobin (Hp) A serum protein that scavenges hemoglobin.

Heme (Hm) A metal ion, customarily iron in the Fe(II) state, chelated in a tetrapyrrole ring.

Hemopexin A serum protein that strongly binds heme.

Hemophore (Hbp) A secreted bacterial protein that shuttles environmental heme to the bacterial surface.

Lactoferrin (LF) A glycoprotein present in the mucosal secretions and phagocytic cells of vertebrates that binds and transports iron.

Siderophore A small molecule secreted by bacteria and fungi that chelates environmental Fe(III) and, as the ferrisiderophore, then binds to the microbial surface.

Transferrin (TF) Iron-binding and transport protein found in the serum and lymph of vertebrates.

Abbreviation

BFR	Bacterioferritin
Fes	Ferrienterobactin esterase
FTN	Ferritin
Hbp	Hemophore
Hm	Heme
Hp	Haptoglobin
LF	Lactoferrin
OH	Hydroxyl radical
TF	Transferrin

Defining Statement

Bacteria are able to obtain iron from diverse sources by employing a variety of transporters. These assimilation systems are described, as is the necessity for their precise regulation and the mechanisms by which this is achieved. The roles of iron in pathogenicity and primary fueling reactions are also summarized.

Introduction

A knowledge of iron metabolism is essential for a complete understanding of bacterial growth and survival and pathogenesis of bacterial pathogens. Although bacteria need relatively low concentrations of iron ($5 \mu\text{mol l}^{-1}$) for maximum growth and survival, iron functions as cofactors of enzymes in forms of ferrous ion, ferric ions, Fe-S clusters, and Hm. Thus, iron is necessary for processes such as electron transport, nitrogen fixation, removal of toxic forms of oxygen, synthesis of DNA precursors, tRNA modifications, ribosome modification, and syntheses of certain amino acids and tricarboxylic acid cycle intermediates; some bacteria can even oxidize iron to obtain energy (and, conversely, other bacteria use iron as a terminal electron acceptor). Iron is such a valuable and versatile nutrient that only a few prokaryotes, such as the lactic acid bacteria, can manage without it.

The redox couple, Fe(II)/Fe(III), can have a range of potentials of -300 – $+700$ mV, depending on the nature of the ligands and the environment surrounding the coordinated iron ions.

[☆]*Change History:* December 2014. B Lei updated the sections of Iron Uptake and Iron-Dependent Regulation, expanded the further reading list, and added Figure 2.

This article is a reprint of C.F. Earhart, Benfang Lei, Iron Metabolism, *Reference Module in Biomedical Sciences*, Elsevier, 2015.

A major consideration in iron metabolism is that, although iron is abundant on the surface of the earth, it is relatively unavailable. At neutral pH and in an oxidizing environment, which includes many common microbial habitats, iron exists in the +3 valence state and, as such, is extremely insoluble. For a microbe inhabiting an animal host, iron availability is restricted by the presence of iron storage and transport proteins, such as ferritin (FTN), lactoferrin (LF), and transferrin (TF). Thus, although relatively low concentrations of iron ($5 \mu\text{mol l}^{-1}$) are generally sufficient for maximum growth yields, bacteria frequently find themselves in iron-deficient environments and must devote a significant amount of their resources to obtaining this metal. Also important is the fact that it is possible for bacteria to suffer from iron overload and iron assimilation must, therefore, be precisely controlled. This article covers prokaryotic iron metabolism only. Descriptions of fungal iron assimilation are included in the reviews by Guerinet, 1994 and Leong and Winkelmann, 1998.

Iron Uptake

Bacterial iron assimilation occurs by a great variety of pathways, presumably because (1) transport systems were unnecessary for iron uptake until relatively late in evolution, when the atmosphere became oxidizing and iron became insoluble, and (2) a number of sources can serve as iron suppliers. In addition, many bacteria have multiple iron uptake systems. This enables them to obtain iron in diverse environments and from several sources. It is not rare to find bacteria with six or more high-affinity iron transport systems, and genome sequencing has shown additional systems may be present but defective. The large number and types of transport systems and variations among closely related bacteria make generalizations regarding iron uptake difficult, even within a species.

Bacteria can obtain iron from a variety of sources but, regardless of its origin, iron must be transported through the several microbial surface layers to reach the cytoplasm. For Gram-negative bacteria, these layers minimally include an outer membrane, a layer of peptidoglycan, and an innermost cytoplasmic membrane. The peptidoglycan cell wall is located in the periplasm, the space between the outer and inner membranes. Gram-positive cells, in contrast, may contain only a thick, highly crosslinked peptidoglycan cell wall external to the cytoplasmic membrane. Because of these distinct extracellular structures, Gram-positive and Gram-negative bacteria employ different mechanisms to relay iron and iron complexes through the surface layer(s). However, regardless of iron sources or forms and transport systems, uptake processes usually involve specific ATP-binding cassette (ABC) transporters that bring iron ions, ferrisiderophore, or Hm across the cytoplasmic membrane in both Gram-negative and Gram-positive bacteria. ABC transporters consist of a peripheral cytoplasmic membrane ATPase, present in two copies and possessing a defining ATP-binding site motif, and two hydrophobic cytoplasmic membrane proteins. The latter proteins can be similar, distinct polypeptides, one large fusion protein, or a homodimer. In addition, iron transporters have a component exterior to the cytoplasmic membrane. For Gram-negative cells, the component is a periplasmic binding protein, which recognizes the iron substrate and presents it to the cytoplasmic membrane complex. In Gram-positive cells, the periplasmic protein is replaced by a lipoprotein tethered in the cytoplasmic membrane but protruding into the peptidoglycan region.

Iron and Heme Uptake in Gram-Negative Bacteria

General pathway in gram-negative bacteria

A great variety of iron transport systems can be distinguished on the basis of the iron source and the form in which iron is mobilized but, in general, they follow a generalized pattern (Figure 1). Thus, for iron complexed to a carrier, first, passage through the outer

Figure 1 Generalized high-affinity iron transport system of Gram-negative bacteria. The three basic components are shown; they include: (a) an outer-membrane receptor protein; (b) a TonB system for energizing the receptor protein; and (c) a periplasmic binding protein-dependent ABC transporter, located in the cytoplasmic membrane. OM, outer membrane; PG, peptidoglycan; CM, cytoplasmic membrane. See text for details.

Table 1 Consensus sequences related to iron

Fur binding site (Fur box, iron box)	G	A	T	A	A	T	G	A	T	A	A	T	C	A	T	A	T
DtxR binding site	T	A	A	G	G	T	A	A	G	C	T	A	A	C	A	T	A
		T								G					T		

^aPositions two and five are the most conserved. Position three is the most variable; Hyd indicates hydrophobic amino acid (Ile, Leu, Val, Met, Phe).

membrane requires an outer membrane receptor protein whose synthesis is iron-regulated. A receptor protein has specificity for and binds a given iron-carrier complex and is sometimes synthesized in abundance only when that particular iron complex is available. In the best-studied cases, receptor proteins have been shown to be gated pores. Second, to permit entry of complexed or free iron into the periplasm, cytoplasmic membrane proteins TonB, ExbB, and ExbD are required. These proteins function as a group to utilize the electrochemical potential of the cytoplasmic membrane to open the gated receptor pores, permitting iron and iron complexes to pass into the periplasm. Generally, each bacterium has just one set of TonB/Exb proteins, capable of interacting with multiple receptors, but *Vibrio cholerae* and *Pseudomonas aeruginosa* have two distinct TonB systems. TonB is anchored in the cytoplasmic membrane but spans the periplasmic space, so as to be able to physically contact all receptors that require it. ExbB has three transmembrane domains and is present primarily in the cytoplasm, while ExbD has only one transmembrane segment and extends into the periplasm. Determination of the details by which TonB and its accessory proteins act is an area of active research. A straightforward mechanism would have ExbB sense the proton-motive force and, with ExbD, use it to induce a conformational change in TonB, which, in turn, could bring about by physical contact allosteric changes in outer-membrane receptors. TonB-dependent receptors have a heptapeptide (TonB box) near their N-termini that is thought to serve as a recognition sequence (Table 1). Third, transport across the cytoplasmic membrane employs an ABC transporter.

In summary, entry of iron into the cytoplasm of Gram-negative bacteria requires an outer-membrane receptor protein, a TonB system, and an ABC transporter. Passage through the outer and cytoplasmic membranes depends on the proton-motive force and ATP, respectively. Outer-membrane receptor proteins bind just one specific iron complex, TonB systems have broad specificity, and ABC transporters often specifically recognize different iron complexes.

Siderophore-mediated systems

A major mechanism by which bacteria obtain iron is through the production and secretion of small (600–1000 Da) iron-chelating molecules termed siderophores. More than 500 different siderophores have been isolated and characterized, but they can generally be classified as being either of the catecholate or of the hydroxamate type. A recent surprise was the observation that in some bacteria the common siderophore enterobactin is further modified by the addition of one or two sugar (glucose) molecules. Glucosylated derivatives of enterobactin and its breakdown products are termed salmochelins. Siderophores are synthesized in iron-deficient environments; after release from cells, siderophores bind iron and the siderophore–iron complex is subsequently internalized using the general type of transport system that has been described.

Siderophore biosynthesis is an interesting and growing area of research. Siderophores, generally, are built up of common amino acids, nonprotein amino acids, and hydroxy acids and, although they contain amide bonds, their synthesis does not involve ribosomes. Instead, a thiotemplate process with strong similarities to that employed for the synthesis of certain peptide antibiotics is used. Nonribosomal peptide synthetases link activated precursors to the enzyme-bound cofactor 4'-phosphopantetheine (P-pant). The thioesterified precursors are then covalently linked by amide bonds in the sequence determined by their position on the synthetase. The synthetase enzymes can be huge; in some cases, molecular weights of greater than 350 000 have been reported. Also, studies on siderophore biosynthesis resulted in the discovery of a new class of enzymes, the phosphopantetheinyl transferases, which donate the P-pant to the peptide synthetases. This essential posttranslational modification of synthetases permits them to bind activated precursors and then join the precursors together to yield the final product.

Other molecules, which do not meet the rigorous definition of siderophores, can also provide iron to cells by means of specific outer-membrane receptor proteins acting in concert with binding protein-dependent ABC transporters. Citrate, when present in environmental concentrations of greater than 0.1 mmol l⁻¹, is one such molecule, as are dihydroxybenzoic acid, a precursor of the common siderophore enterobactin, and dihydroxybenzoylserine, a breakdown product of enterobactin.

How newly synthesized siderophores are secreted is the least-known aspect of the siderophore cycle. In the cases where the process is somewhat understood, cytoplasmic membrane efflux pumps are required. There are a variety of such pumps, most of which are powered by the proton-motive force, such as members of the MFS and RND families, but the ABC transporters use ATP. Representatives of all three of these families have been implicated in siderophore release. Specifically, species of the genera *Erwinia*, *Vibrio*, *Bordetella*, and *Legionella* use MFS exporters; *Pseudomonas* may use an RND exporter and siderophore secretion in *Mycobacteria smegmatis* requires the ExiT protein (an ABC transporter). Efflux pumps generally have broad substrate specificity, and this makes it possible that in some bacteria several pumps may be able to extrude a given siderophore. Such redundancy may pertain in *E. coli*, where two proteins, EntS and TolC, affect enterobactin secretion. EntS is a member of the MFS family of transporters. Secretion of enterobactin but not its breakdown products is reduced in cells bearing an *entS* mutation. TolC is an

outer-membrane protein that is necessary for the functioning of many efflux pumps. *E. coli tolC* strains secrete no enterobactin. A current model postulates that there are two paths for enterobactin release and that both require TolC. The less commonly used path secretes enterobactin directly from the cytoplasm to the environment. Any of the several efflux pumps can probably be used to move enterobactin through a continuous channel that terminates with TolC. The more frequently used route may employ two steps; EntS acts first to place enterobactin in the periplasm and a second transporter, probably of the RND family, completes the secretion process via TolC.

Uptake of ferrous and ferric ions

Ferrous iron transport is useful to microbes capable of inhabiting oxygen-restricted environments, such as swamps, intestines, and marshes, or acidic locales, where reduced iron is stable and soluble. Fe(II) can enter the periplasm by means of pores in the outer membrane, and from there, bacteria have a variety of systems capable of transporting it through the inner membrane. Some of these cytoplasmic membrane transporters have broad specificity for transition metals and only low affinity for ferrous iron. However, systems that function only with Fe(II) as substrate are known. One such system that is essential in some bacteria is encoded by the *feo* operon (*feoABC*). FeoB is a large cytoplasmic membrane protein that hydrolyzes GTP and functions optimally in conjunction with its two smaller coregulated proteins, FeoA and FeoC. Many bacteria have *feo* genes, as does *Methanococcus jannaschii*. The latter finding is of interest in that *M. jannaschii* is classified in the domain Archaea, not in the domain Bacteria. Another widely distributed group of Fe(II) transporter proteins are members of the OFeT (oxidase-dependent iron transporter) family first observed in lower eukaryotes. Details regarding Fe(II) transport are lacking for both the Feo system and the bacterial members of the OFeT family. Finally, certain aerotolerant bacteria, such as the Gram-positive organism *Streptococcus mutans*, obtain iron by using a reductase exposed on the cell exterior to convert surface-bound Fe(III) to Fe(II). A ferrous ion transporter then delivers the iron to the cytoplasm.

A ferric iron acquisition system of the ABC type is present in a number of Gram-negative genera including *Serratia*, where it was discovered and termed Sfu type transport, *Haemophilus*, *Yersinia*, *Actinobacillus*, and *Neisseria*. A periplasmic binding protein accepts Fe(III) and presents it to the cytoplasmic components of the transporter, which internalize the iron. Ferric iron transporters can also function in concert with uptake systems that have outer-membrane components. In these cases, they become the terminal portion of the assimilation path. Thus, iron is removed from TF and LF at the outer membrane (see following), a process which requires a receptor and active TonB system, and then translocated into the cytoplasm by the ferric transporter. Also, iron can be transferred from citrate to a periplasmic binding protein for entry into the cytoplasm.

Uptake of iron from heme

The vast majority of iron in animals is present intracellularly as heme (Hm). Hm, in turn, serves as a prosthetic group of proteins, primarily hemoglobin (Hb), but also myoglobin and Hm-containing proteins such as cytochromes. Cell lysis is necessary for the release of these proteins. Freed Hb, such as that present following hemolysis of erythrocytes, is bound by the serum glycoprotein haptoglobin (Hp). Hb not bound by Hp can oxidize, in the process releasing Hm from globin. This extracellular Hm is bound by the plasma protein hemopexin and, less specifically, by serum albumin. Therefore, extracellular Hm, available as a possible source of iron (and Hm), occurs infrequently by itself as it is usually bound to Hb, Hb–Hp complexes, or hemopexin. In no case has a siderophore been able to scavenge iron from Hm. However, as will be described, each Hm source is capable of being utilized by one or another group of bacteria. These uptake systems vary greatly.

Iron assimilation pathways that recognize free Hm resemble those for iron–siderophore complexes; they require (1) an outer-membrane receptor protein that is TonB-dependent and (2) for cytoplasmic membrane passage, an ABC transporter. For several of these systems, including those of *Yersinia enterocolitica*, *V. cholerae*, and *Shigella dysenteriae*, it has been deduced that the entire Hm molecule enters the cytoplasm. In these cases, Hm supported porphyrin growth requirements, as well as provided iron. Pathogenic *E. coli* strains can often obtain iron from Hm but *E. coli* laboratory strains cannot. However, laboratory strains have an ABC transporter for dipeptides that can also recognize Hm. Therefore, recombinant laboratory strains that have a foreign outer-membrane receptor for Hm can use Hm as an iron source. Presumably, this dipeptide transporter can serve an auxiliary role in transporting Hm in bacteria that have a designated Hm transporter.

Several genera can remove Hm from Hb. *Neisseria* and *Haemophilus* spp. have TonB-dependent Hb-binding proteins in their outer membranes. Remarkably, both of these genera have additional TonB-dependent receptors that function in iron acquisition from Hb–Hp complexes. Each of these Hb–Hp receptors may consist of two different proteins. A different mechanism for the initial steps in obtaining iron from Hm or Hb is found in *Serratia marcescens*. This organism uses an ABC transporter to secrete a small protein (HasA) that functions as a hemophore (Hbp). That is, HasA is an extracellular Hm-binding protein that is necessary for the uptake of Hm, either free or bound to Hb. It shuttles its bound Hm to an outer-membrane receptor (HasR). *E. coli* strains harboring the virulence plasmid pColV-K30 also secrete an Hbp. Unlike HasA, this Hbp is autotransported out of the cell and is bifunctional. It has protease activity, degrading Hb as well as binding and transporting the released Hm. A chromosomally encoded outer-membrane receptor protein (ChuA), required for the well-known *E. coli* pathogen O157:H7 to use Hb or Hm, may be the Hbp–Hm receptor.

Only *Haemophilus* strains are known to utilize Hm associated with hemopexin. The system is not well characterized but three genes are required and one appears to encode a large secreted Hbp (HxuA). HxuA binds Hm–hemopexin, removes the Hm, and carries Hm to an outer-membrane receptor. The other two genes encode proteins concerned with the secretion of HxuA. Like all

Haemophilus Hm transport systems (free Hm, Hb:Hp, Hm:albumin), the Hm-hemopexin system requires a functional TonB protein.

Acquisition of iron from transferrin and lactoferrin

TF and LF are extracellular iron transport molecules present in the fluids of many vertebrates; each of these related glycoproteins can bind two ferric ions. Many siderophores are capable of removing iron from these glycoproteins. Members of the *Neisseriaceae*, *Pasteurellaceae*, and *Moraxellaceae* produce no siderophores, however, and instead they have specific TonB-dependent outer-membrane receptors that bind these transport proteins. An ABC transporter necessary for all nonheme iron uptake pathways (TF, LF, or iron chelates) is present in *Neisseria*; iron from these sources passes through the outer membrane and is bound by periplasmic protein FbpA, prior to entry into the cytoplasm. Outer-membrane TF and LF receptors are unusual in that they appear to be bipartite; one protein has the characteristics of a typical TonB-dependent receptor, while the second is a surface-exposed lipoprotein. These receptors in *Neisseria* and *Haemophilus* show high specificity for glycoproteins of their normal hosts, such as humans.

Low-affinity iron transport

The high-affinity iron transport systems described above are generally not expressed in environments containing more than $5\text{--}10\ \mu\text{mol l}^{-1}$ iron. Remarkably, the means by which bacteria assimilate iron in such iron-replete environments, oxic or anoxic, is not known. This so-called low-affinity iron uptake may first require that iron be in the Fe(II) form. Ascorbic acid, which reduces Fe(III), stimulates low-affinity iron uptake. Fe(II) could be assimilated either (1) by the repressed levels of the *feo* system proteins or (2) by a cytoplasmic membrane transporter with broad specificity for divalent cations, such as the CorA protein of *E. coli* and *Salmonella typhimurium*. Also, several types of small molecules (monocatecholates, α -keto acids, and α -hydroxy acids) can, in certain genera, function as siderophores; they could mobilize extracellular ferric iron and, using a variety of transporters, provide iron.

Iron and Heme Uptake in Gram-Positive Bacteria

Gram-positive bacteria do not have the outer membrane but has a thick cell wall envelope. Because of this distinct extracellular structure, Gram-positive bacteria have evolved iron and heme acquisition processes that have distinct features from those in Gram-negative bacteria. Most notably, acquisition of ferrisiderophores only requires ABC transporters, and cell wall-linked proteins are produced to relay heme through the thick cell wall envelope to heme-specific ABC transporters in Gram-positive bacteria.

Siderophore-mediated iron acquisition

Specific ABC transporters appear to be sufficient to acquire ferrisiderophores in Gram-positive bacteria. Apparently, ferric siderophore complexes can diffuse through the cell wall to reach their ABC transporters. Siderophore-mediated iron acquisition is common in Gram-positive bacteria. *Staphylococcus aureus* produces two hydroxycarboxylate-type siderophores, staphyloferrin A and staphyloferrin B, which are transported by the ABC transporters HtsABC and SirABC, respectively. *B. subtilis* produces a catechol-type siderophore bacillibactin, and its ferric complex is taken up by the ABC transporter FeuABC. *Bacillus anthracis* produces two catecholate siderophores, petrobactin and bacillibactin, and petrobactin acquisition involves lipoprotein FpuA and redundant permeases FpuB and FatCD and ATPases FpuC, FpuD, and FatE. *Mycobacterium tuberculosis* produces mycobactins and carboxymycobactins.

Siderophore production is not detected in some streptococci, including Group A *Streptococcus* and *Streptococcus pneumoniae*. *Streptococcus equi* subsp. *equi* produces a siderophore. However, the capacity of *S. equi* to produce siderophore is acquired from an integrative conjugative element. These findings support the notion that bacteria in the Streptococcaceae family do not have a siderophore-producing system. However, members of the Streptococcaceae family produce specific ABC transporters to take up certain ferrisiderophores. Group A *Streptococcus*, Group B *Streptococcus*, and *Streptococcus pneumoniae* produce FtsABCD, FhuABCD, and PiaABCD, respectively, to acquire ferric complexes with hydroxamate-type ferrisiderophores, such as ferriferichrome. Even though streptococci usually do not have the capacity to produce siderophores, they have the capacity to acquire iron using siderophores produced by other bacteria in the same habitats.

Utilization of transferrin iron in gram-positive bacteria

Whether Gram-positive pathogens are able to use ferric transferrin as an iron source depends on whether they produce siderophores. *S. aureus* can use transferrin iron for growth, which can be extracted by either staphyloferrin A or staphyloferrin B and transported through their cognate ABC transporters. In contrast, ferric transferrin cannot support Group A *Streptococcus* and *S. pneumoniae* growth *in vitro*. However, pathogens without siderophore production may be able to use transferrin iron by using exogenous siderophore in infection with multiple bacterial species

Heme uptake pathways

Hm is sequestered tightly in proteins. Free Hm and hemoproteins to be used as iron sources appear to be unable to diffuse through the cell wall envelope to reach specific ABC transporters in Gram-positive bacteria. Thus, Gram-positive bacteria produce surface proteins to assimilate heme from hemoproteins and relay it to heme-specific ABC transporters.

Significant progress has been made in the last decade in the understanding of the machinery, pathway, and biochemical mechanism, and structural basis for heme acquisition process in Gram-positive bacteria, including Group A *Streptococcus*, *S. aureus*

Figure 2 The proposed pathway of Hm acquisition from metHb by the *Staphylococcus aureus* Isd system. The arrows indicate the direction of direct heme transfer. Heme transfer from IsdB to IsdC represented by the dotted arrow may be prevented *in vivo* by their physical locations in the cell wall. The structure models of the proteins were from the coordinates 2Q8Q, 2ITF, 2O6P, and 1HHO. This figure was originally published in *Journal of Biological Chemistry* 283 (2008) 18450–18460.

and *B. anthracis*. The heme acquisition machinery of Group A *Streptococcus* consists of the surface proteins Shr and Shp and heme-specific ABC transporter HtsABC. The heme acquisition system in *S. aureus* is composed of the iron-regulated surface determinant (Isd) proteins, including the surface proteins IsdA, IsdB, IsdH, and IsdC and ABC transporter IsdDEF. Group A *Streptococcus* HtsA and *S. aureus* IsdE share a high level of sequence homology. However, Shr and Shp have no overall homology with the Isd surface proteins, and Shp can rapidly and directly donate its heme to the HtsA homologue of *Streptococcus equi* but not to *S. aureus* IsdE. The heme acquisition systems of Group A *Streptococcus* and *S. aureus* must have diverged enough to be considered as two distinct systems even they might have evolved from a common ancestor. *B. anthracis* has the homologues of *S. aureus* IsdC and ABC transporter IsdDEF and two other surface proteins IsdX2 and BslK but the *B. anthracis* system uses secreted hemophore IsdX1, thereby representing a distinct heme acquisition system in Gram-positive bacteria.

Relay of Hm from hemoglobin to ABC transporter by surface proteins has been demonstrated *in vitro* for the Group A *Streptococcus* and *S. aureus* heme acquisition systems. Hm is directly and rapidly transferred from human Hb to IsdB, from IsdB to IsdA and IsdC, from IsdA to IsdC, and from IsdC to IsdE, and IsdB and IsdC at catalytic levels dramatically enhance heme transfer from metHb to IsdE. These findings support the heme acquisition pathway of $\text{Hb} \rightarrow \text{IsdB} \rightarrow \text{IsdA} \rightarrow \text{IsdC} \rightarrow \text{IsdDEF}$ in *S. aureus* (Figure 2). IsdH is also a hemoglobin receptor and is able to rapidly extract heme from metHb and donate it to IsdA. Thus, IsdB and IsdH appear to be redundant. The heme acquisition pathway of $\text{Hb} \rightarrow \text{Shr} \rightarrow \text{Shp} \rightarrow \text{HtsABC}$ in Group A *Streptococcus* is established based on the findings that rapid and direct heme transfer is observed only in the Hb/apoShr, holoShr/apoShp, and holoShp/apoHtsA reactions. In the *B. anthracis* system, IsdX1 can scavenge heme from metHb and transfer heme to IsdX2 and IsdC, and IsdX2 can also scavenge heme from Hb. Whether IsdC transfers heme to IsdE in *B. anthracis* is not known yet. Thus, the Hm acquisition pathway in *B. anthracis* has not been fully established yet.

Surface proteins and the lipoprotein of Hm-specific ABC transporters involved in Hm acquisition bind Hm at extremely high affinity. Hm-binding surface proteins usually contain one or more the NEAT-Iron Transporter (NEAT) domain. NEAT proteins were first identified in Gram-positive pathogens Group A *Streptococcus*, *S. aureus*, *B. anthracis*, *Clostridium perfringens* and *Listeria monocytogenes* and in non-pathogens *Bacillus jalodurans* and *Listeria innocua*. Characterized NEAT proteins have one or more NEAT domains, which bind Hm or interact with other proteins. A recent bioinformatic analysis identified 343 putative NEAT domains within 185 proteins. These NEAT proteins are mostly encoded by Gram-positive bacteria of the phylum Firmicutes, and analysis of metagenomic data from the Human Microbiome Project suggests that NEAT domain proteins are generally restricted to pathogenic species in human. However, NEAT proteins are also present in environmental and soil organisms. NEAT protein-mediated heme acquisition may occur in environmental and soil Gram-positive bacteria.

Heme transfer mechanisms

Kinetic, structural, and functional analyses indicate that Hm is transferred rapidly and directly from one protein to another along Hm acquisition pathways. Hm transfer follows a concerted two-step kinetic mechanism in the Shp/HtsA and IsdA/IsdC reactions. In this mechanism, the heme donors Shp and IsdA first form an activated complex with HtsA and IsdC, respectively, to allow direct Hm transfers that are >4000 times faster than simple Hm dissociation from these Hm donors. In the Shp/HtsA reaction, the axial ligand residues Met79 and His229 for Hm iron in HtsA specifically displace the axial ligand residues Met66 and Met153 of Shp, respectively, and the HtsA axial residues are involved in the cleavage of the axial bonds of Hm iron in Shp.

The Hb receptor IsdH of *S. aureus* has three NEAT domains. A truncated fragment of IsdH containing NEAT 2 and NEAT 3 and the linker between them is able to acquire Hm from Hb *in vitro*. Based on the crystal structure of a complex of Hb with the NEAT 2-linker-NEAT 3 IsdH fragment, NEAT 2 binds α/β globin through a site distant from the globin Hm pocket and positions NEAT 3 perfectly for the Hm pocket in NEAT 3 to acquire Hm from Hb. A similar mechanism is most likely followed in the reaction between Hb and IsdB. IsdB has two NEAT domains. The first NEAT domain (NEAT 1) in the N-terminal region interacts with Hm, and the second NEAT domain (NEAT 2) is the Hm-binding domain. A disordered loop in NEAT 1 in solution is critical for extraction of Hb Hm by IsdB both *in vitro* and *in vivo*. The other non-NEAT domains in the N-terminal regions critically contribute to the rapid kinetics and/or favorable equilibrium of the Hb/IsdB reaction. It is proposed that the non-heme-binding domains of IsdB interact with Hb and NEAT 2 to bring the Hm pockets of Hb and IsdB together to facilitate direct extraction of Hm from Hb by the Hm pocket in NEAT 2.

Cytosolic Iron Release from Siderophore and Hm

Prior to cellular usage iron is released from high affinity complexes with siderophores and protoporphyrin after ferric siderophore and Hm are transported across the cytoplasmic membrane. Release of iron from siderophores can be achieved through two kinds of enzyme-catalyzed reactions: hydrolysis of siderophore and reduction of ferric ion into ferrous ion. Pathogenic *salmonella* and *E. coli* produce ferrisiderophore esterases Fes and IroD to hydrolyze ferric enterobactin and its glucosylated derivatives called salmochelins, respectively, for the release of ferric ion from enterobactin and salmochelins. Gram-positive *Bacillus subtilis* produces ferric bacillibactin esterase BesA that can hydrolyze both ferric bacillibactin and ferric enterobactin whereas Fes cannot hydrolyze ferric bacillibactin.

Ferrisiderophore reductases convert high affinity ferric siderophore complexes into low-affinity ferrous complexes from which iron is moved to other iron binding sites of equal or higher affinities in the cytosol. Reduced flavin generated by flavin reductases or reduced flavin cofactor in nitroreductases can reduce various ferrisiderophores *in vitro*. These flavin reductases and nitroreductases belong to the NAD(P)H:flavin oxidoreductase superfamily. These enzymes have broad specificity and their abundance is not affected by iron availability. Bacteria can also produce specific ferrisiderophore reductases. *E. coli* ferric hydroxamate reductase FhuF uses a [2Fe-2S] cluster as a cofactor to reduce ferric hydroxamates but not ferric enterobactin. FchR produced by Gram-positive *Bacillus halodurans* catalyzes the reduction of ferric hydroxamates. Specific ferric triscatecholate reductases are also described recently. ViuB, which belongs to the NAD(P)H:flavin oxidoreductase superfamily, is required for ferric vibriobactin utilization in *V. cholerae* and can complement the function of Fes in *E. coli* though Fes does not complement a ViuB mutant of *V. cholerae*. ViuB homologs are present in various Gram-positive and Gram-negative bacteria and may play a critical role in iron assimilation for bacteria that utilize high affinity catecholate siderophores.

Like conventional Hm oxygenases in eukaryotes, Hm oxygenases in *C. diphtheriae*, *N. meningitidis*, and *Pseudomonas aeruginosa* catalyze the degradation of Hm, forming biliverdin, ferrous ion, and CO. The Hm oxygenases, such as IsdG and IsdI in *S. aureus* and *B. anthracis* and MhuD in *Mycobacterium tuberculosis* also oxidize Hm to release ferrous iron. Unlike the conventional Hm oxygenases, the IsdG/I proteins convert heme to a chromophore called staphylobilin with the release of iron and formaldehyde, and MhuD degrades protoporphyrin to a product called mycobilin that keeps the meso-carbon as an aldehyde.

Intracellular 'Free' and Stored Iron

Two types of iron storage proteins, FTN and bacterioferritin (BFR), are found in bacteria. BFRs are a subfamily of FTNs, distinguished by the fact that they contain Hm units. Like eukaryotic FTNs, the bacterial proteins are large (~500 000 Da) and composed of 24 subunits.

The actual role of these proteins is uncertain. Unlike eukaryotic FTNs, which can accommodate over 4000 iron atoms, maximum iron contents for FTN and BFR are much less. BFR is synthesized primarily during periods of slow or no growth and may serve as an iron donor upon resumption of growth. FTN, on the other hand, is present at a constant low level throughout the growth cycle and, for at least *E. coli* and *Campylobacter jejuni*, has been shown to protect against iron-catalyzed oxidative damage.

A major uncertainty regarding bacterial iron metabolism is the distribution and form of much of the intracellular iron. Even the quantity of iron in a bacterium is unclear; for the well-studied organism *E. coli*, estimates of the number of iron atoms per cell range from 100 000 to 750 000. In a variety of bacteria, Hm-containing proteins account for less than 10% of the total iron, in contrast to the situation in animals. Iron-sulfur proteins also contain 10% or less of the bacterial iron, as do FTN and BFR when cells grown under iron-deficient conditions are examined. The remainder of the bacterial iron, the majority, exists in a mobile pool about which little is known. One report has suggested that the ions of the mobile Fe(II) pool are bound by a complex of phosphorylated sugars. It is this mobile iron that is presumably responsible for iron regulation and for the toxic effects of iron overload. Whether or not iron passes through this pool before being placed by ferrochelatase into protoporphyrin IX to form Hm, before incorporation into Fe-S clusters of proteins by unknown means, or before being converted into Fe(III) by the ferroxidase activity of BFR and FTN and deposited in the core of these molecules is unknown.

A most unusual role for intracellular iron occurs in the magnetotactic bacteria. These organisms contain internal magnets termed magnetosomes. Magnetosomes are 30–120 nm crystals of magnetite (Fe₃O₄) or greigite (Fe₃S₄) enclosed by a membrane; they exist

as chains and enable magnetotactic bacteria to sense and orient along geomagnetic fields. Magnetotactic bacteria are a diverse group but all are flagellated Gram-negative cells that favor microaerophilic environments in stratified natural waters. In conjunction with other tactic responses, magnetosomes are thought to assist these bacteria in finding their optimal environmental niche by guiding the cells downward following magnetic lines of force. The biogenesis of magnetosomes is not well documented but what is known indicates that it has several unusual aspects. The magnetosome membrane originates as an invagination of the cytoplasmic membrane, and is thus a phospholipid bilayer, and attains a distinctive protein complement that includes 20 magnetosome-specific proteins, most of which are encoded on a 130 kb magnetosome genomic island. Although magnetotactic bacteria have normal iron assimilation components, the uptake and biomineralization of iron for magnetosomes may occur by a distinct pathway that functions only in microoxic or anoxic conditions. Nonmagnetic mutants of a marine vibrio were found to be damaged in a gene for a periplasmic copper-containing protein, which was hypothesized to be part of a complex that transported iron for magnetite synthesis. Also, the assembly of magnetosomes into chains apparently requires cytoskeletal filaments composed of a new species of actin-like protein. Iron can constitute 4% of the dry weight of magnetotactic bacteria.

Iron-Dependent Regulation

Regulation of Iron Uptake

Genes encoding proteins necessary for high-affinity iron uptake are regulated by iron availability. The key regulatory protein in most bacteria, Gram-negative and Gram-positive bacteria whose DNA has a low GC content, is Fur. Fur, a small, histidine-rich polypeptide, is an aporepressor; in the presence of its corepressor Fe(II), it binds DNA. The holorepressor binds operators termed iron boxes, which are AT-rich 19 bp sequences with dyad symmetry (Table 1). Iron boxes are located in promoters of iron-regulated genes, such that steric hindrance prevents the repressor and RNA polymerase from binding simultaneously. Adequate intracellular iron supplies thus prevent transcription of genes for transport proteins and siderophore biosynthetic enzymes. A typical bacterium will have 50–100 such Fur-regulated genes.

Gram-positive organisms whose DNA has a high GC content, like *Corynebacterium* and *Streptomyces*, have no Fur but instead accomplish iron-regulated transcriptional control with DtxR proteins. The protein sequence of DtxR is unlike that of Fur but DtxR nonetheless functions in a Fur-like manner. Fe(II)–DtxR binding sites are 19 bp palindromes (Table 1) and are positioned in the promoters of genes they regulate.

Fur-like and DtxR-like proteins have repeatedly been selected to ensure that bacteria have appropriate levels of specific metals. Genome sequencing has demonstrated that many microbes have several proteins related to Fur and DtxR. Bacteria with Fur-regulated iron metabolism often have DtxR-controlled manganese uptake.

Some iron transport systems are produced only in iron-deficient environments that contain their cognate ferrisiderophores. That is, the systems are synthesized only if the intracellular iron concentration, as sensed by Fur, is low and if their specific ferrisiderophore is bound to the cell. As established in the ferridicitrate system of *E. coli*, the specific outer-membrane receptor must be present, as must a functional TonB system. Binding of ferrisiderophore to the receptor transmits a signal to a cytoplasmic membrane protein that has both periplasmic and cytoplasmic domains. The signal is then passed to a cytoplasmic sigma factor-like protein that, upon activation, associates with RNA polymerase and stimulates transcription of the necessary transport genes. Unique regulatory elements for these systems include an outer-membrane receptor capable of interacting with the cytoplasmic membrane protein, the cytoplasmic membrane protein, and its partner sigma-like factor. Among Pseudomonads, this dual regulation of specific iron transport systems by Fur and surface binding of the relevant ferrisiderophore is common.

Posttranscriptional Regulation of Intracellular Iron Usage

When iron is limited, numerous iron-containing proteins are down-regulated, including succinate dehydrogenase, aconitase, cytochrome C, and biosynthetic enzymes for heme, cysteine, and branched chain amino acids. The repression of iron-using enzymes in *E. coli* is mediated by a Fur-controlled small RNA, RyhB. RyhB synthesis is negatively regulated by Fur in iron-replete conditions. When iron becomes scarce, RyhB is expressed and stabilized by the RNA chaperone Hfq. The RyhB sRNA pairs with an mRNA target to block translation, and the sRNA-mRNA complex is recognized and degraded by the multi-protein complex RNA degradosome. RyhB-like small RNAs have been identified in many bacterial species, such as *P. aeruginosa*, *V. cholera*, *Shigella flexneri*, *N. meningitidis*, *S. enterica*, and *B. subtilis*.

Regulation of Responses to Various Environment

In addition to directly controlling genes for iron assimilation and storage and indirectly controlling genes for iron-using enzymes in metabolism, Fur contributes to responses to and survival in a particular environment. Fur is involved in the defenses against oxidative stress. Iron mediates the cytotoxic effect of reactive oxygen species. H_2O_2 reacts with iron to form the reactive and damaging hydroxyl radical via the Fenton reaction, and superoxide is converted to H_2O_2 and increases iron concentration of iron by attacking iron-sulfur proteins. Fur deletion mutants are more sensitive to hydrogen peroxide and show increased oxidative DNA damage and mutations under aerobic conditions. H_2O_2 and superoxide activate the regulators OxyR and SoxS, respectively. Besides

inducing transcription of a set of antioxidant genes, OxyR and SoxS also enhance the expression of Fur. Superoxide dismutase (Sod) is commonly regulated by Fur. SodA, SodB, and SodC utilize Mn(II), Fe(II), and Cu(II) or Zn(II), respectively, as their metal cofactor. *N. gonorrhoeae* sod is activated directly by Fur. In *E. coli*, sodA is directly repressed by Fur-iron whereas sodB is indirectly activated by Fur through the action of RyhB. In *H. pylori*, sodB is directly repressed by Fur in the absence of iron. Fur transcripts are also affected by regulators that sense carbon source (cAMP–CAP) and oxygen availability (ArcC). Fur is also involved in the acid tolerance response.

Fur and Fur-like proteins play a role in colonization and virulence in diverse pathogens. Diphtheria toxin belongs to a family of ADP-ribosyltransferase toxins that transfer ADP-ribose to eukaryotic proteins to inactivate target proteins and promote bacterial pathogenesis. The diphtheria toxin gene is directly regulated by DtxR. Shiga-like toxin and hemolysin in *E. coli* are repressed by Fur. Fur negatively regulates hemolysis production and an outer membrane virulence determinant IrgA in *V. cholerae*. In *N. gonorrhoeae*, Fur directly interacts with the promoters of 11 outer membrane proteins that aid in adherence to and invasion of host cells. MtsR, an iron/manganese-dependent metalloregulator in Group A *Streptococcus*, directly regulates streptokinase that activates host plasminogen to dissolve fibrin for pathogen dissemination. In *S. aureus*, many virulence factors are positively regulated by Fur. These virulence factors include coagulase, superantigen exotoxins, and two virulence factors known as Eap and Emp that are involved in biofilm formation. Fur is required for the expression of the two-component regulatory system SaeRS, which regulates the expression of many virulence factors of *S. aureus*.

Iron in Primary Fueling Reactions

Some bacteria can use the oxidation of iron compounds as their primary energy source. Bacteria capable of using inorganic, rather than organic, molecules for their fueling reactions are termed chemolithotrophs, and iron-oxidizing bacteria are a major group in this nutritional category. Iron-oxidizing bacteria typically live in acidic, aerobic environments rich in both reduced-iron and -sulfur compounds; they grow poorly at pH values greater than 4. Among other things, low pH is critical in keeping Fe(II) from being spontaneously oxidized to Fe(III).

Thiobacillus ferrooxidans, the best-studied microbe in this group, oxidizes iron using proteins in the cell envelope. An outer-membrane complex oxidizes iron to the ferric form, and a periplasmic protein transfers the electrons to cytochromes in the cytoplasmic membrane; these, in turn, pass the electrons to oxygen, the ultimate electron acceptor, in the cytoplasm.

T. ferrooxidans is a major cause of water pollution, specifically, acid mine drainage. Ferrous sulfide is common in many coal and ore sites, and its chemical and bacterial oxidation leads to both acidification and addition of dissolved metals to the water. Downstream, as the pH of the mine water becomes less acidic, insoluble ferric precipitates form.

In contrast to the relatively few bacteria that can oxidize iron as the initial step in generating energy, in the absence of oxygen many bacteria, notably *Shewanella* species and members of the *Geobacteriaceae* family, can use Fe(III) as the terminal electron acceptor in fueling reactions. This dissimilatory reduction of iron is a form of anaerobic respiration and is of interest for several reasons. It has the geochemical significance of solubilizing iron, and it is likely to represent a very early form of respiration, as all of the last common ancestors of modern organisms can reduce Fe(III) (using dihydrogen as the electron donor). Also, dissimilatory iron reduction is widespread among hyperthermophilic archaea, which is additional evidence for the ancient origin of this form of respiration. This extracellular respiration in which electrons are transferred from the cell to external substrates occurs in a manner similar to the electron flow in iron-oxidizing bacteria but in reverse. Electrons are thought to pass from menaquinone in the cytoplasmic membrane to small, soluble periplasmic electron-carrier proteins and then to terminal reductases, generally *c*-type cytochromes, in the outer membrane. From there electrons can be transferred directly or indirectly to minerals. Two types of direct transfer are known; the terminal reductases either bind or interact directly with extracellular iron and, alternatively, electron transfer takes place by means of surface appendages. The latter process has been reported in *Geobacter sulfurreducens* and *Shewanella oneidensis*, which are believed to produce specialized pili (nanowires) through which electrons pass to reduce insoluble Fe(III) compounds. Indirect electron transfer to extracellular iron can employ (1) metal chelators, such as citrate and nitrilotriacetic acid, to solubilize ferric iron and transport it to the cell for reduction or (2) electron shuttles, such as flavins, which transfer electrons from the cell to the static Fe(III) oxide substrates. Mechanistic details for all of the external reductive reactions are being determined. Interest in extracellular electron transfer to Fe(III) (and Mn(IV)) oxides is great because of the environmental significance and possible practical applications in bioremediation and electricity generation. The latter involves transferring electrons from organic compounds to electrodes via bacteria and their nanowires. Also, iron reduction by *Shewanella oneidensis* is remarkable in that surface appendages called pili are required. The electrons that reduce extracellular insoluble Fe(III) compounds pass through the pili, in the process generating a detectable current. The term ‘electricigens’ is used to describe bacteria that produce electricity.

Iron and Pathogenicity

A major stimulus to current studies on microbial iron metabolism is their medical significance. A brief review of the genera studied in the section titled ‘Iron Uptake’ will emphasize this fact.

Bacterial pathogens find themselves in an iron-deficient environment when they invade a eukaryotic host; conditions facilitating their acquisition of iron would be expected to increase virulence. Several general observations support this idea. Humans with higher than normal iron levels show enhanced susceptibility to bacterial infections. Similarly, at least 20 bacterial pathogens are more virulent when their animal host is injected with iron compounds prior to infection. Because excess iron can have a number of effects, including some that are detrimental to host immune defenses, these data are somewhat ambiguous. They are bolstered, however, by *in vitro* experiments showing that the antibacterial effects of body fluids can be uniquely reversed by iron supplementation.

Bacteria must synthesize an appropriate iron uptake system to overcome the bacteriostatic conditions in their hosts. Pathogens that multiply extracellularly, such as in blood or on mucosal surfaces, and that do not lyse host cells must be able to obtain iron from TF or LF. This can be accomplished by siderophores or by TF- or LF-specific receptor proteins. Septicemic bacteria with defective siderophore systems are, in fact, less virulent. On the other hand, the major source of iron for intracellular pathogens is Hm, and siderophore-deficient mutants of these organisms are still virulent. The required iron is taken from Hm compounds in this case.

For many pathogens, it has been difficult to identify specific iron uptake systems that are essential for their virulence. The multiplicity of means for assimilating iron in every species studied complicates such attempts. However, when all high-affinity systems are inactivated by the use of mutations in *tonB*, *S. typhimurium*, *V. cholerae*, and *Haemophilus influenzae* are avirulent. That a specific iron assimilation pathway can be a virulence factor has now been demonstrated for a number of pathogens. The type of transport system critical for virulence varies with the pathogen and can be species-specific. Thus, *N. meningitidis* lacking its outer-membrane hemoglobin receptor (HmbR) is attenuated for meningococcal infection in infant rats. *N. gonorrhoeae* with no functional TF receptor is unable to initiate urethritis in humans. High-affinity ferrous iron transport (FeoB-mediated) is important for *H. pylori* colonization of the gastric mucosa of mice and a functional siderophore system is required for *Yersinia pestis* virulence in mice. *Y. pestis* strains unable to either synthesize or transport the siderophore yersiniabactin are avirulent. A siderophore system is also a virulence factor in the fish pathogen *Vibrio anguillarum*. This marine microbe infects salmonid fish; approximately ten bacteria per fish are sufficient to cause vibriosis, a fatal disease characterized by hemorrhagic septicemia. A plasmid-encoded iron uptake system that uses the siderophore anguibactin is necessary for virulence.

Finally, many pathogens utilize the low iron concentrations in the host as an environmental signal to synthesize virulence factors. Fur and DtxR-like proteins control not only iron acquisition systems but also the synthesis of toxins and hemolysins in these organisms.

Conclusion

Interest in microbial iron metabolism continues to expand. Initial work in the field provided evidence regarding the diverse means by which bacteria obtain iron, began the elucidation of the critical role of iron in bacterial metabolism, and uncovered the means and necessity for the precise regulation of iron assimilation. The importance of iron in bacterial pathogenesis became well established and is now considered in all studies of prokaryotic pathogens. Basic studies utilizing *E. coli* and its relatives, while still incomplete and still yielding unexpected results, such as the existence of glucosylated derivatives of enterobactin, have given way to studies of less understood, and more difficult to cultivate, organisms. Studies of magnetotactic bacteria and particularly magnetosome biogenesis promise to uncover processes for controlling biomineralization and to provide insight into organelle formation. Possible biotechnology ramifications of investigations of dissimilatory iron reduction are likewise exciting. The recognition of the broad and central role played by the environmental interactions between bacteria and iron has led to the entry of geologists, ecologists, environmental and chemical engineers, and physicists as well as other disparate professions into the field. There is every possibility of multiple fascinating new discoveries.

Glossary

Alarmone Small guanine nucleotide molecules (i.e., ppGpp and pppGpp) that are produced by bacteria under stress and regulate numerous cellular activities in response. These alarmones are signals for the stringent response that occurs in the presence of amino acid starvation.

Atypical pneumonia Infection of the pulmonary airspace that fails to produce the sudden onset and rapid clinical course associated with pneumococcal (“typical”) pneumonia.

BCYE-a Buffered charcoal yeast extract agar supplemented with α-ketoglutarate. This medium is enriched for the isolation of *Legionella* species, and it also contains supplemental iron salts and cysteine.

Carrión’s disease A geographically isolated disease transmitted by sandflies infected with *Bartonella bacilliformis*, including a severe febrile illness with hemolysis (Oroya fever) and chronic disseminated skin lesions (verruca peruana).

Endocarditis An infection of the internal surface of the heart, usually manifested as a collection of fibrin, platelets, and microorganisms deposited on one of the valve leaflets.

Endocytic pathway The process by which substances that are ingested by the cell are directed to their final intracellular destination. In the case of ingested bacteria, this refers to the steps in the delivery of the phagosome to the lysosomal compartment.

Hematophagous Literally, ‘blood-eating’; referring to the behaviors of some biting arthropods.

Hemolytic anemia A loss of erythrocytes in the bloodstream by virtue of a process that causes their rupture or inappropriate removal from the circulation.

Abbreviations

ACES	N-(2-Acetamido)-2-aminoethanesulfonic acid
BA	Bacillary angiomatosis
CDC	Centers for Disease Control & Prevention

ER	Endoplasmic reticulum
IFA	Indirect fluorescent antibody
T4SS	Type IV Secretion System
TLR	Toll-like receptor

Introduction

This article focuses on two bacterial genera, *Bartonella*, and *Legionella*. These bacteria are both fastidious Gram-negative pathogens, each of which requires specialized conditions for *in vitro* cultivation. However, as pathogens, they demonstrate distinct pathophysiology and epidemiologic features.

Specifically, *Legionellae* live in aquatic environments and soil, and grow within resident protozoa. They also exist within biofilm in fresh water plumbing systems, providing one route of aerosol exposure to susceptible humans. When inhaled in the form of

[☆]*Change History:* December 2014. JE Kirby updated the text for the entire article and further readings.

This article is an update of N.C. Engleberg, *Legionella*, *Bartonella*, *Haemophilus*, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 170–181.

aerosols from environmental water sources, they use their profoundly adaptive machinery evolved to parasitize numerous types of protozoa to grow intracellularly within alveolar macrophages in human lungs and thereby adventitiously cause a life threatening pneumonia. Quite often *Legionella* pneumonia occurs in an outbreak setting linked to a common source exposure. In contrast, *Bartonella* organisms are arthropod-borne pathogens that cause chronic systemic infection in mammals and in part persist through colonization of host red blood cells. Human infection occurs through exposure to infected animals or associated blood sucking arthropod vectors. Disease manifestations depend on the immune status of the host, and may range from febrile illness to induction of angioproliferative tumors.

Hence these two pathogens represent two unique disease causing entities, an environmental bacteria (*Legionella*) that fortuitously sets up a dead-end infection in humans and a zoonotic pathogen (*Bartonella*). The remainder of this article focuses on the specific factors that mediate the distinct life cycle and pathophysiologic features of these two bacterial species.

Legionella

The Organism

The Legionellaceae are aerobic, Gram-negative bacilli that use amino acids rather than carbohydrates as their preferred energy source. There are nearly 50 species within the genus *Legionella*, the majority of which have been isolated only from environmental, rather than clinical sources. In the environment, these organisms may inhabit complex communities composed of multiple bacterial species that grow within biofilms. They have been isolated from waters with temperatures ranging from 5 to 50 °C; however, they can grow to abundance at the warmer end of this spectrum, particularly in water distribution systems, water heaters, whirl pool baths, and most notoriously evaporative cooling towers. *Legionella* bacteria are natural parasites of free-living protozoa that dwell in lakes, ponds, or streams and graze on bacteria in biofilms. When *Legionella* are taken up by protozoa, such as the amoebal species *Hartmannella* or *Acanthamoeba*, they are able to evade intracellular degradation and grow within specialized vacuoles in these single-cell eukaryotes. The coexistence of *Legionella* bacteria and a competent protozoan hosts in potable water systems appears to be a prerequisite for the creation of *Legionella* containing aerosols, which may result in human infections.

Legionella pneumophila is the most frequently encountered and the best-studied species, as it is associated with most human infection, usually in the form of an atypical pneumonia designated Legionnaires' disease (see 'History'). There are 16 distinct serogroups of *L. pneumophila*, with serogroup 1 accounting for the majority of recognized Legionnaires' disease cases in the United States, Europe and Japan. Interestingly, *Legionella longbeachae* causes approximately half of the cases in Australia and New Zealand, and is also prevalent in Southeast Asia. In contrast to *L. pneumophila*, infection by this species is highly associated with exposure to potting soil and composts. At least twenty-four other species have caused human infections (e.g., *Legionella micdadei*, *Legionella dumoffi*, and *Legionella bozemanii*), but they are much less prevalent and most often isolated from hospitalized or severely immunocompromised patients. All of the potential pathogens must be able to survive and grow within macrophages in order to cause productive infection in the lungs of mammals, presumably by exploiting similar pathogenic mechanisms used to parasitize their natural protozoan hosts. Interestingly, dependence on the intracellular niche for growth is a feature also shared by the most closely related non-*Legionella* species, *Coxiella burnetii*, a pathogen that also causes atypical pneumonia.

The Legionellaceae are fastidious in their growth requirements *in vitro*. They are susceptible to noxious substances generated during the autoclaving of agar. Growth is also inhibited by concentration of sodium ions found in almost all standard bacterial growth media. Thus, semisolid media are typically prepared with added charcoal to absorb toxic substances and an organic buffer to avoid addition of sodium salts. Specifically, in addition to charcoal, the standard *Legionella* growth media contains yeast extract, to supply amino acids; ACES, an organic buffer; and lastly supplemental L-cysteine and soluble iron, required for growth. α -ketoglutarate is also often added as a growth enhancer. Media is buffered to a pH of 6.9 with addition of potassium hydroxide either prior to or after autoclaving. Typically, *L. pneumophila* colonies can be isolated on this buffered charcoal yeast extract α -ketoglutarate agar media (BCYE- α) in 2–5 days. As most normal flora grow abundantly on this rich media, antibiotics may be added to help select for *Legionella* spp. when culturing non-sterile respiratory specimens. Liquid culture of *Legionella* may be performed in ACES Yeast Extract (AYE) medium prepared with the same constituents as BCYE- α with the exception that insoluble activated charcoal is not added, and the medium is filter sterilized rather than autoclaved to avoid generation of toxic growth inhibitors.

History

Awareness of the Legionellaceae began after a large outbreak in a downtown Philadelphia hotel that hosted an American Legion Convention in 1976. Over 200 people were affected, and the case-fatality rate was 15%. The severe respiratory disease affecting the conventioners thus became known as "Legionnaires' disease." However, the etiologic agent, *L. pneumophila* serogroup 1, was not isolated and characterized until the following year at the Centers for Disease Control and Prevention (CDC). The organism was initially passed from postmortem clinical specimens into guinea pigs, subsequently on embryonated chicken eggs, and finally on specialized, enriched media. The association of this organism with disease was suggested by the development of antibodies to this organism in affected patients, detected by using an indirect fluorescent antibody (IFA) test with the fixed bacteria as the capture antigen. The use of the IFA test also permitted CDC investigators to screen stored human sera associated with prior unexplained outbreaks of respiratory infection, several of which were retrospectively diagnosed as Legionnaires' disease, one of which had occurred at a different convention at the same Philadelphia hotel.

In addition to severe pulmonary disease, outbreaks of self-limited, flu-like illnesses were associated with *L. pneumophila* serogroup 1 seroconversion. This relatively benign syndromic response to *Legionella* organisms has been named 'Pontiac fever' (see below for details). Since 1977, the list of *L. pneumophila* serogroups and non-*L. pneumophila* species has gradually lengthened, as new organisms were isolated from patients and from environmental sources.

Epidemiology

With refinements in the media and serology, it was possible to show that Legionnaires' disease occurs both in discrete outbreaks and in sporadic cases. Water distribution systems were shown to be the predominant environmental sources of human infection (e.g., potable water sources, showers, sprayers, decorative fountains, and evaporative cooling towers). When outbreaks occur from these sources, exposure of humans is usually very common, but disease among exposed individuals is relatively rare. Accordingly, attack rates in these outbreaks are typically ~5%, suggesting that most humans can clear an inhaled inoculum of *L. pneumophila* without developing disease. In contrast, most individuals who develop Legionnaires' disease in outbreak situations have one or more underlying predispositions (e.g., advanced age, smoking history, lung disease, or immunosuppression).

Pathogenesis – Intracellular Infection

Intracellular infection of free-living amoebae in the natural aquatic environment appears to be a strategy that permits *Legionella* organisms to survive and grow among complex bacterial communities that are frequently grazed upon by protozoa. Mutants that cannot grow in protozoa have been isolated. Whether these mutants could survive in the aquatic environment is unknown. However, it is clear from laboratory animal experiments that infection in the lungs requires the capacity to infect and to grow in alveolar macrophages. Mutants that cannot grow in eukaryotic cells cannot cause disease. Because *Legionella* bacteria are not transmitted between mammals, it is presumed that the mechanisms that permit growth and development in macrophages evolved in protozoa.

Transmissive and Replicative Phases

L. pneumophila alternate between two distinct phases to complete their intracellular life cycle. The regulation of these phases occurs through a complex cascade of gene expression or suppression, reviewed by Molofsky and Swanson. A key determinant of the phase is the abundance of free amino acids, as amino acids are the primary nutrient source for *L. pneumophila*, and alterations of fatty acid metabolism thought to occur during the terminal stages of intracellular growth. When nutrients are abundant, the posttranscriptional regulator CsrA represses traits associated with transmission and cellular invasion (e.g., flagella synthesis and motility, lysosomal evasion, stress resistance, and cytotoxicity) and promotes bacterial division. In contrast, when nutrients are scarce, *Legionella* are triggered to increase production of the stringent response alarmone, (p)ppGpp, through an altered balance of synthase and hydrolase activities for this signaling nucleotide. This alarmone in turn increases the level of the alternative sigma factor, RpoS, and stimulates a virulence-associated two-component system, LetA/LetS. The latter system induces expression of small noncoding regulator RNAs that bind to and effectively inactivate, CsrA, a transcriptional repressor of transmissive phase genes. Together with the abundance of RpoS, these regulators induce the expression of the transmissive traits mentioned above and inhibit bacterial replication.

Similar to log-phase growth in nutrient broth, the intracellular niche provides abundant amino acids to the bacteria. Consequently, in both log-phase and intracellular growth, the organisms replicate rapidly, but they do not express flagellar motility or any of the traits required to establish infection in host cells. If harvested from these growth states, bacteria are unable to initiate cell infection de novo. As a broth culture enters stationary phase, or as the intracellular bacteria exhaust available amino acid and fatty acid stores of the cell, (p)ppGpp is produced, the bacteria stop growing, and they express a phenotype that will permit productive infection of a new host cell – that is motility, invasion, and host cell altering virulence factors that promote productive infection. Hence, bacteria grown to stationary phase in broth culture or harvested from host cells during terminal stages of infection are efficient in establishing infection in new host cells.

Intracellular Life Cycle

Flagellate *L. pneumophila* (in the transmissive phase) are promptly taken up by macrophages on contact (Figure 1, step 1). Several types of phagocytosis have been described including uptake into spacious phagosomes, uptake by a zippering mechanism, and more rarely a novel coiling mechanism in which a pseudopod wraps itself around the bacterium, drawing the organism into the host cell (Figure 2(a)). During and after ingestion, the bacterium alters the normal endocytic maturation pathway and in doing so avoids trafficking to the digestive pit of the host cell, the lysosome. Instead, the *L. pneumophila*-containing vacuole matures by acquisition of membranous intracellular organelle components from the exocytic rather than the endocytic pathway. (Figure 1, steps 2 and 3). Specifically, the cellular proteins, Arf1 and Rab1, which normally attract vesicles from the endoplasmic reticulum (ER) to the cis-Golgi, are instead recruited to the membrane of the *L. pneumophila*-containing vacuole. Within a few hours, the vacuolar membrane enlarges by fusion with redirected ER vesicles. In addition, the membrane becomes studded circumferentially with ribosomes (Figure 2(b)). In essence, the *Legionella pneumophila* phagosome becomes part of the ER. Importantly, the ER vesicles contain nascent proteins, and

Figure 1 Schematic diagram of events in the *Legionella pneumophila* life cycle in macrophages. Flagellate bacteria in the transmissive phase are taken up by the cell, sometimes by a process of ‘coiling’ phagocytosis (1). Virulent bacteria within the early phagosome, (2) evade phagolysosomal fusion (2a), and associate with other membranous organelles (3). Endoplasmic reticulum (ER) bearing ribosomes associate with the *L. pneumophila*-containing vacuole, the bacteria are converted into the replicative phase, and intracellular replication begins (3 and 4). At 24 h, large vacuoles displace the cytoplasm of the cell, and the bacteria are converted again into the transmissive phase (5) before they are released from the cell to swim free to the next host cell (6). N.C. Engleberg *Legionella, Bartonella, Haemophilus*, Encyclopedia of Microbiology, 2009, 170–181, <http://dx.doi.org/10.1016/B978-012373944-5.00194-2>.

Figure 2 Electron micrographs showing key events in *L. pneumophila* replication in macrophages. (a) An electron-dense bacterium is seen surrounded by a pseudopod coil as it is taken into the cell. (b) Bacteria are seen in individual phagosomes studded with ribosomes (arrows) after endoplasmic reticulum (ER) vesicle recruitment. (c) As intracellular replication proceeds, increasing numbers of bacteria are seen in enlarging vacuoles (arrows). N.C. Engleberg *Legionella, Bartonella, Haemophilus*, Encyclopedia of Microbiology, 2009, 170–181, <http://dx.doi.org/10.1016/B978-012373944-5.00194-2>.

it is speculated that the ribosomes may provide polypeptides that the bacteria cleave proteolytically (secreted protease being abundantly liberated) and utilize as nutrients. Presumably, amino acids are likely to be abundant at this stage, since the bacteria convert into the nonflagellated, replicative phase and begin to grow and to divide. As replication proceeds and bacterial numbers increase, some fusion with lysosomes may occur; however, late in the course of intracellular replication, there is little deleterious effect of lysosomal contents on bacterial viability. After 24 h, the cell contains large membrane-bound compartments filled with bacteria, many of which have converted again into the transmissive phase (Figure 1, step 5; Figure 2(c)). Presumably, the resources of the host cell available to the intracellular bacteria are exhausted at this point, leading to an increase in the alarmone, (p)ppGpp, which triggers the phase transition. Bacteria in the transmissive phase produce a cytotoxin that induces the release of bacteria from the cell. Finally, the motile progeny are then free to seek out a new host cell (Figure 1, step 6).

Mechanisms of Intracellular Survival

Survival of *L. pneumophila* in both macrophages and amoebae depends on a type IV secretion system (T4SS), designated as Dot/Icm, and on the effectors that this system translocates into the host cell cytoplasm. Mutations that abrogate the functions of this secretion system result in the inability of an individual bacterium to escape the endosomal–lysosomal pathway, and instead the ingested bacteria are directed to the lysosome within 5 min (Figures 1 and 2(a)). Approximately 300 substrate proteins are now known to be transported by this system, and the functions of some are either known or strongly suspected (Table 1). Substrate proteins have been identified using various screens for T4SS-dependent protein translocation. Alternatively, other investigators devised genetic screens to detect specific functions that are thought to mediate the intracellular life cycle events. For example, a genetic screen was used to identify mutants that are unable to recruit Rab1 to the *L. pneumophila*-containing vacuole. Another

Table 1 Selected substrates of the Dot/Icm type IV secretion system

Function	Protein	Mechanism
Vacuolar modification	RalF	Exchange factor for Arf GTPase
	DrrA	Exchange factor for Rab1 GTPase
	LidA	Binds to Rab1 GTPase
	SidJ	Facilitates recruitment of ER vesicles
Inhibition of lysosome fusion	VipA	Inhibits lysosomal trafficking (in yeast)
	VipF	Inhibits lysosomal trafficking (in yeast)
	VipD	Inhibits lysosomal trafficking (in yeast)
Prevention of host cell apoptosis	SdhA	Forestalls host cell apoptosis
	SidF	Forestalls host cell apoptosis
Release from the host cell	LepA	Facilitates lytic release of bacteria from protozoa
	LepB	Facilitates lytic release of bacteria from protozoa; inactivates Rab1

method identified genes encoding proteins that bind to Rab1. A third approach identified mutations that interfere with membrane trafficking in yeast cells. Lastly, translocated effectors could sometimes be identified from genomic sequence based on homology with eukaryotic functional domains. In fact, all told, about 10% of the *Legionella* genome appears to be “eukaryotic” in nature and likely devoted to cooptation of host cells.

Examples of identified effectors include two Dot/Icm-dependent proteins that redirect secretory vesicles to the *L. pneumophila* vacuole (RalF and DrrA; **Table 1**). Other Dot/Icm substrates have been shown to interfere with phagosome–lysosome fusion; stimulate host cell antiapoptotic factors to postpone cell death until bacterial replication is exhausted; and facilitate the release of progeny bacteria from the cell (**Table 1**). Many of the substrate proteins translocated by Dot/Icm have redundant functions, presumably to ensure functionality in diverse protozoan hosts. The functions of many translocated effectors remain yet to be determined. As *Legionella* have been evolving creative ways to coopt the host cell for eons, discovery of new translocated effector functions will undoubtedly yield novel insights into host cell biology.

Consequences of Infection (Legionnaires' Disease)

Infection of humans with *L. pneumophila* is usually acquired by the inhalation of aerosolized bacteria directly into the lower airways. Aspiration of contaminated drinking water is also considered a means of inoculating organisms deep within the lung. The minimal infectious inoculum and form of the infectious particle (e.g., individual bacteria; biofilm fragments; protozoa; protozoan cysts; or isolated protozoan vesicles containing bacteria) are unknown. Of interest, *L. pneumophila* within amoebae are more infectious than plate-grown bacteria alone, when equivalent inocula were administered by intratracheal injection in laboratory animals. However, relative infectivity of free organisms living in their natural, relatively nutrient poor fresh water environment was not studied. Therefore, the jury is still out on the importance of different forms of *Legionella* for human infection.

After the initial infection of pulmonary alveolar macrophages with *L. pneumophila*, inflammatory cells (monocytes and neutrophils) are recruited into the lung. Interestingly, *Legionella* appears in contrast to other bacterial agents of acute pneumonia to induce a relatively macrophage rich inflammatory response - i.e., recruiting the exact type of inflammatory cell required for propagation in the host. Eventually inflammation in alveoli coalesce into microabscesses which may spill through the pores of Khan and distal bronchiole connections to extend the pneumonia within lobules and/or lobes of the lung.

Most of the lung damage is likely to be a product of the vigorous inflammatory response. However, bacteria may contribute directly to damage through specific toxic activity. For example, the organisms produce a lipopolysaccharide that is mildly endotoxic. They also elaborate a major extracellular protease that is potentially cytotoxic; however, experimentally, protease knockouts mutants cause similar disease making suspected contributions of this protease less likely. Another characteristic lung pathology in Legionnaires' disease is leukocytoclasia: visually, fields of chewed up pieces of inflammatory cells, likely both apoptotic and necrotic cell in origin. This detritus may represent the outcome of the prominent contact-dependent macrophage cytotoxicity noted *in vitro* in the presence of modestly high infection ratios. Interestingly, this cytotoxicity, although initially thought to be directly related to the action of the dot/icm type IV secretion on host cell membranes, appears in large part to be a secondary event. Specifically bacterial flagellin adventitiously translocated into the host cell via the same T4SS leads to host cell inflammasome activation and consequent host cell self-immolation (technically known as pyroapoptosis) through host cell-actuated perforation of its own cell membrane.

Legionella pneumonia may be severe, and locally destructive, and lead to permanent structural damage to the lung (fibrosis or scarring) after resolution. Ultimately, the outcome of infection is dependent on the balance of pathogen virulence, host response to infection, and appropriate treatment.

Host Response to Infection

The host can mount an innate response to *L. pneumophila*. At a cellular level in mouse macrophage hosts cells, this response is, in part, dependent on the presence of assembled flagella that trigger cytosolic pattern recognition receptors (e.g., naip-5) and inflammasome

activation as mentioned above. Inflammasome activation, if not leading to direct pyroptosis of host cells, may limit infection through several less drastic mechanisms: (1) increased targeting of pathogens to lysosomal compartments; (2) enhanced degradation of organisms; and (3) a cascade of cytokine release that ultimately leads to interferon gamma (IFN- γ) production and resulting sequestration of intracellular iron so vital to the fecundity of this organism. The relative importance of inflammasome activation in controlling human infection is a matter of current investigation. Interestingly, *L. pneumophila* also produces anti-apoptotic factors that directly oppose the self-sacrifice of individually infected cells that might otherwise limit availability of an intracellular growth compartment. Cell surface pathogen recognition receptors, specifically Toll-Like Receptors (TLR), must also play an important role in the host response. Supporting this notion, several TLR polymorphisms have been strongly implicated in disease susceptibility. Lastly, we should not understate the importance of innate mechanisms of a more macroscopic nature. Specifically, normal hosts with good mucociliary clearance may merely sweep inhaled organisms out of the lungs.

Once infection has been established, the growth of *L. pneumophila* within macrophages must be controlled by a Th1-dependent adaptive immune response with IFN- γ and tumor necrosis factor alpha (TNF- α) as major effectors. The restriction of intracellular growth caused by IFN- γ is a result of the sequestration of intracellular iron induced by this cytokine, as mentioned above, and can be overcome experimentally by providing abundant transferrin-iron. The role of humoral immunity in Legionnaires' disease appears secondary (as *Legionella* is primarily an intracellular pathogen) and at all events would require prior exposure to have an impact on acute disease. However, when present, specific antibodies may help target any extracellular bacteria to neutrophils, where intracellular replication does not occur, rather than mononuclear phagocytes, where infection may flourish.

Taken together, these observations may explain why Legionnaires' disease tends to occur in a subset of smokers or individuals with chronic lung disease (altered physical clearance); and those with suboptimal innate or adaptive immune responses including the elderly and immunosuppressed patients.

Pontiac Fever

After the discovery of *L. pneumophila* in 1977, an outbreak of illness at the Pontiac, Michigan county health department in 1968 was retrospectively found to be associated with seroconversion to *L. pneumophila* serogroup 1. The epidemic illness in Pontiac, that affected 95% of the building occupants, was remarkably different from Legionnaires' disease. It was noted that the patients reported self-limited, flu-like symptoms that lasted for only 2–5 days. Both healthy and high-risk individuals were exposed and became ill, but none died. In more recent outbreaks of Pontiac fever, *Legionella* bacteria have not been isolated from affected patients, suggesting that illness may result from inhaling nonviable organisms. The exact pathogenesis of Pontiac fever remains a mystery.

Diagnosis, Treatment, and Prevention

Clinically, Legionnaires' disease presents as a pneumonia that may demonstrate focal, lobular or lobar consolidation on chest X-ray; bibasilar lower lobe pneumonia is typical. Respiratory symptoms are often preceded by a flu-like prodrome. While symptomatically not readily distinguishable from other causes of pneumonia, patients do have an unusual predilection to develop low blood sodium levels (hyponatremia) and diarrhea. The reasons for these seemingly quixotic physiological associations are unknown.

Legionnaires' disease can be diagnosed definitively by the culture isolation of *Legionella* bacteria from the respiratory tract, although sensitivity of culture diagnosis is suboptimal. Moreover, from a practical point of view, culture diagnosis is often not helpful clinically, because colonies generally do not appear until 3–4 days of incubation on selective media. A brief acid treatment of sputa samples has been reported to increase yield from respiratory samples by reducing competition from the much faster growing normal respiratory flora, but has not been widely adopted in clinical settings. Colonies isolated on BCYE- α media or BCYE- α selective media with appropriate speckled opalescent appearance can be presumptively confirmed as *Legionella* based on several *in vitro* phenotypes. Specifically, *Legionella* stain faintly as Gram negative rods with a typical safrinin counterstain or more strongly with a basic fuchsin counterstain. Importantly, *Legionella* is one of the rare bacteria that fail to grow on other standard clinical laboratory medium (chocolate and blood agar), based on the aforementioned inhibitors in autoclaved agar and the strong inhibition provided by levels of sodium chloride present. Therefore, a Gram negative organism with appropriate colonial characteristics and Gram stain morphology can be presumptively reported out as *Legionella* if it fails to grow on passage on chocolate and/or blood agar, or on BCYE medium lacking L-cysteine. Serotyping and/or speciation can then be accomplished by immunofluorescence or agglutination, and molecular analysis, respectively. Of note, cysteine-dependent *Francisella tularensis* can grow particularly well on BCYE- α and may not passage well on blood agar. Identification of this dangerous alternative pathogen may be suspected based on characteristic Gram stain showing minute coccobacilli.

Currently, infection with *L. pneumophila* serogroup 1 can be diagnosed rapidly and with great sensitivity by a urine antigen test that detects serogroup-specific lipopolysaccharide epitopes. This specific assay is useful in clinical practice because it is rapid and accurate and also because serogroup 1 accounts for approximately 70–80% of Legionnaires' disease in most locations. Newly introduced nucleic acid amplification tests offer the ability to rapidly detect *Legionella pneumophila*, potentially in the context of multiplex respiratory panels, that simultaneously detect viral and bacterial causes of atypical pneumonia.

Although *Legionella* organisms are susceptible to most antibiotics *in vitro*, many agents (e.g., all β -lactams and aminoglycosides) are of little or no use *in vivo* because they do not efficiently penetrate into cells where *Legionella* bacterial replication takes place. Antibiotics that are concentrated intracellularly to high levels – fluoroquinolones rifampin, and advanced-generation macrolides (e.g., azithromycin) – are clinically useful. There is currently no vaccine against Legionnaires' disease.

Environmental testing for *Legionella* may be warranted to locate the source of human exposure in an outbreak setting. Of special concern are water sources in hospitals where especially susceptible patient populations are often present. Special testing methods that make use filtration of one liter volumes of suspect water sources and swabs of suspect piping, and subsequent culture on selective media are generally used to isolate environmental *Legionella*. Typing of environmental and patients strains, for example, through pulsed field gel electrophoresis or multi-locus sequencing typing is then used to establish that the environmental *Legionella* and patient isolates are clonal, thereby providing impetus for environmental remediation. Environmental remediation may be accomplished through hyperchlorination and/or thermal pasteurization, that is raising water temperatures either intermittently or permanently, to kill off organisms and their protozoan hosts.

Bartonella

The Organism

The *Bartonellae* are Gram-negative bacilli of the class α -proteobacteria, within the order, Rhizobiales, and therefore most closely related to *Brucella*, *Rhizobium*, and *Agrobacterium* spp. *Bartonella* species have evolved to infect and establish carriage in specific mammalian host species, although they may also cause disease when transferred to a nonnatural host. In the native host, the specific anatomic sites contributing to long-term persistence is not known; however, the bacteria may persist in the bloodstream without producing overt sepsis by replicating and surviving for long periods within erythrocytes. Their presence in the bloodstream (either extracellular or within erythrocytes, so called hemotropic infection) enables transmission between natural hosts via blood-sucking arthropod vector intermediates. Numerous *Bartonella* species have been identified, but only a handful have been observed to infect humans. The most well-known and prevalent causes of human disease are *Bartonella henselae*, *Bartonella bacilliformis*, and *Bartonella quintana*. However, *Bartonellae* are notoriously difficult to culture. With recent advent of more sensitive culture and molecular techniques there has been increasing awareness of zoonotic infection with diverse species, some of which may be specific to certain locales and zoonotic exposures, for example *B. tamiae* infection in Thailand likely related to exposure to rodents or their ectoparasites, and *B. vinsonii* *susp. berkhoffii* infections in veterinarians exposed with frequency to canines.

History

In parts of Andean South America, a warty skin disorder known as verruga peruana (Peruvian wart) was recognized since pre-Columbian times. An epidemic of febrile illness associated with hemolytic anemia (known as Oroya fever) occurred among railroad workers in a similar geographic distribution during the late nineteenth century. The common etiology of these two disorders was established in a famous auto-experiment performed by a Peruvian medical student. Daniel Carrión injected himself with lesional material from a patient with verruga peruana; he then developed Oroya fever and died, thereby establishing verruga peruana and Oroya fever as manifestations of the same disease. Subsequently, the biphasic disease caused by this organism has been designated “Carrión’s disease” in recognition of Daniel Carrión’s heroic experiment. In 1909, the erythrocyte-associated bacteria that cause Oroya fever were observed by microbiologist Alberto Barton and later designated as *B. bacilliformis*. *B. bacilliformis* was the only recognized member of the genus *Bartonella* for the next 80 years.

Until 1990, bacillary angiomatosis (BA) was an unexplained opportunistic infection of patients with advanced AIDS. It is a disease that causes persistent fever, malaise, and skin lesions reminiscent of verruga peruana. The focal lesions of BA feature abundant proliferation of small blood vessels, infiltration of inflammatory cells, and abundant clumps of silver-staining bacteria within expansive extracellular matrix. The identity of the bacteria in these lesions was revealed by using a set of universal bacterial primers to amplify 16S rDNA from human tissues affected by BA. The sequence of the amplified DNA was then compared with a databank of known 16S RNA sequences. The closest match was with *Rochalimaea quintana*, the cause of Trench fever, a louse-borne infection encountered primarily during World War I. Consequently, the related agent associated with BA was initially placed in the same genus, as *Rochalimaea henselae*. However, when the close identity of both *R. quintana* and *R. henselae* with *B. bacilliformis* and other zoonotic *Bartonella* species was appreciated, all of these agents were reassigned to the genus *Bartonella*, and the genus *Rochalimaea* was eliminated.

Perhaps the most intriguing consequence of the identification and eventual cultivation of *B. henselae* was the discovery that it also caused a more common and benign disease in immunocompetent individuals, that is, CSD. For decades, the etiology of CSD was obscure and widely debated. However, after *B. henselae* was isolated from the tissues of BA patients, it was possible to demonstrate a serologic response to this agent in virtually all patients with CSD. *B. henselae* was also detected in lymph nodes of patients with CSD and in the blood of healthy cats both by cultivation *in vitro* and by PCR. Ironically, the unification of these two disparate pathological entities is like a twentieth century echo of the unification of verruga peruana and Oroya fever, demonstrated by Daniel Carrión’s tragic sacrifice in the name of science 100 years earlier.

Epidemiology

The occurrence and range of human *Bartonella* infection depend on the geographical location of the natural hosts and the vectors of transmission (Table 2). Humans are thought to be the exclusive natural hosts for *B. bacilliformis* and *B. quintana*. *B. bacilliformis*

Table 2 Representative *Bartonella* species, their hosts, and arthropod vectors

Species	Natural host	Arthropod vector	Human disease
<i>Bartonella bacilliformis</i>	Humans	Sandflies	Oroya fever, verruga peruana
<i>Bartonella quintana</i>	Humans	Lice	Urban trench fever, endocarditis, bacillary angiomatosis (BA)
<i>Bartonella henselae</i>	Cats	Fleas	Cat scratch disease (CSD), bacillary angiomatosis (BA), retinitis, endocarditis
<i>Bartonella vinsonii</i> subsp. berkhoffii	Dogs,	Ticks?	Bacteremia, endocarditis

infection is limited geographically to the Western Andean slopes, probably by the distribution of competent sandfly vectors. *B. quintana* is transmitted by the human body louse; the infection is therefore restricted to regions and populations where human infestation with this ectoparasite is common, such as among inner-city homeless populations, refugee encampments, and historically during trench warfare (so called trench or quintan fever during World War I). Because *B. henselae* primarily infects domestic cats and is transmitted by cat fleas, the disease is cosmopolitan in distribution, wherever cats are kept as pets. There are numerous additional *Bartonella* species that primarily infect other small mammals and some large ones too, especially ruminants. Prevalence of infection in some hosts may exceed 50%. However, human contact with these animals and their ectoparasites is either uncommon, or transmission to humans does not occur efficiently. Therefore, human infection is relatively rare.

Pathogenesis

Infection in the natural host

In their natural hosts, most of the *Bartonella* species cause minimal disease manifestations or no disease at all. A notable exception is *B. bacilliformis* infection in humans in which a fatal hemolytic anemia (Oroya fever) can occur. Yet, even with this potentially dangerous infection, there are selected human hosts who become bacteremic, but remain minimally symptomatic. It is not known what factors determine whether a human host will suffer a severe and fatal illness or remain asymptomatic and become part of the reservoir.

The natural host typically becomes infected by the bite of an infected blood-feeding arthropod (Figure 3). Adherence of the organisms to both endothelial and epithelial cells is mediated by trimeric autotransporter adhesins, exemplified by the BadA adhesin in *B. henselae* and the VompA-VompD proteins in *B. quintana*. These proteins are members of the so-called type V secretion systems. The same proteins also mediate adherence to various extracellular matrix components including collagens, fibronectin and laminin. These proteins are remarkably large, indeed for a time BadA was the largest bacterial protein yet described. Interestingly too, they show extensive variation and may become truncated or deleted during infection, potentially as a way to undermine immunological recognition of these prominent, environmentally exposed proteins.

For most species, the primary site of infection may be vascular endothelium at the site of inoculation. This assumption is based on the observation that *Bartonella* bacteria readily proliferate in contact with endothelial cells (the cell type that forms the inner

Figure 3 Infection of *Bartonella* in the natural host. The organism is inoculated into the susceptible host by a biting hematophagous arthropod, for example, sandfly, flea, louse, or ked, depending on the *Bartonella* species. (1) Bacteria adhere to and invade endothelial cells at or near the site of inoculation, (2) creating a primary nidus of intra- or extra-cellular growth and source of synchronized release of bacteria into the circulation every few days. Circulating *Bartonella* organisms infect red blood cells. (3), and grow to large numbers in the bloodstream. (4). Alternatively, some bacteria may reenter endothelial cells or extravascular space to maintain the primary nidus of infection (3a). Infected red blood cells serve as a source for transfer to an uninfected vector arthropod (5) to complete the cycle. N.C. Engleberg *Legionella, Bartonella, Haemophilus*, Encyclopedia of Microbiology, 2009, 170–181, <http://dx.doi.org/10.1016/B978-012373944-5.00194-2>.

lining of blood vessels) *in vitro*, and they are taken up into a membrane-bound vesicle within these cells. Furthermore, organisms are observed preferentially in cat scratch nodes or angioproliferative lesions extracellularly in clusters around small blood vessels, although this colocalization may merely represent organisms caught in transit into and out of the bloodstream.

As with the *L. pneumophila*–host cell interactions described above, *Bartonella*–endothelial cell interactions in most species are mediated by the activity of a type IV secretion system (T4SS). However, the T4SS used by *Bartonella* and *Legionella* are only very distantly related, and are generally considered to fall within two distinct subsets: the type IVa (used by *Bartonella*, *Brucella*, *Rickettsia*, *Anaplasma*, *Agrobacterium*) and IVb (used by *Legionella*, *Coxiella*, *Rickettsiella*) systems, respectively. *Bartonella henselae*'s T4SS system and a set of translocated effector proteins (BepA–G) are involved in the induction of cytoskeletal rearrangements, modulation of intracellular infection, and suppression of apoptosis in endothelial cells. Interestingly, a separate T4SS is essential for the establishment of erythrocyte infection in many *Bartonella* species including *B. henselae* and *B. quintana*. A species-specific T4SS-encoded pilus appears to act as a tether to host-specific red blood cell receptors, thereby permitting efficient red cell invasion, only if pathogen tether and host species receptor match. Therefore, for example, *B. henselae* efficiently invades into red cells of cats but not humans. After invasion, the bacteria persist in erythrocytes until the red blood cells become senescent and are removed from circulation. This is quite a long time since the average life span of a red cell is on the order of four months. In this way, *Bartonellae* can maintain a high enough concentration in blood to facilitate efficient uptake by hematophagous arthropod vectors during a blood meal, and ensure continuation of the transmission cycle.

Notably, *Bartonella* are highly unusual in that they can cause prolonged and relatively high level bloodstream infection without obviously damaging or septic consequences for the host. This is largely without precedence amongst other bacterial pathogens. Several phenomena may contribute to this capability. First, the bacteria may remain sequestered within erythrocytes and in doing so have diminished contact with Toll-like receptors (TLR) on circulating leukocytes. Second, the *Bartonella* lipopolysaccharide is modified to be less capable of triggering innate cytokine induction. Third, at least some *Bartonella* induce the expression of the anti-inflammatory cytokine interleukin-10, which dampens cell-mediated immune responses and facilitates bacterial persistence. Interestingly, in some hosts, a detectable antibody response also fails to develop, despite chronic bacteremia. Taken together, these capabilities and almost certainly others not yet discovered must underlie the highly unusual ability of *Bartonella* to cause silent bacteremia in their natural hosts. Again, this silent infection contrasts markedly with symptomatic chronic bloodstream infections caused by *Brucella* (the nearest pathogenic relative) and other causes of acute and chronic bacterial bloodstream infection.

Interestingly, *B. bacilliformis*, a species that lacks T4SS, causes overt disease in its natural human host. In the absence of help from T4SS, red cell invasion by *B. bacilliformis* relies instead on a flagellar motor-dependent mechanism. Possibly related to this distinct mode of red cell colonization, and in contrast to other *Bartonella* species, *B. bacilliformis* causes contact-dependent lysis of red blood cells *in vitro* and as mentioned previously a severe hemolytic anemia in humans (Orroya fever). Therefore, T4SS-dependent processes may have evolved to allow a more harmonious and perhaps evolutionarily more successful relationship between pathogen and host. Notable in this regard is that the acquisition of T4SS capabilities has been associated with an explosive adaptive radiation of *Bartonella* within mammals.

Infection in an accidental host

Erythrocyte infection is not typically a feature of infection in the accidental host. Consequently, the accidental host may have a localized symptomatic infection at the site of inoculation or a primary infection with septicemia or endocarditis or both. In the case of human *B. henselae* infection, it appears that the immune competency of the host is the most important determinant of disease. Most immunocompetent individuals who are inoculated by a cat scratch (or exposure to cat fleas) develop a minor, transient lesion at the site of inoculation and a highly inflammatory reaction to infection in one or more nearby regional lymph nodes. The host response in lymph nodes may take the form of stellate micro-abscesses surrounded by histiocytes (tissue macrophages); necrotizing granulomas (granulomas with dead cellular material in their center); or suppurative inflammation (pus). The immune response is exuberant and limiting, and consequently bacteria are often difficult to find by microscopy. In CSD, the infection may persist for weeks to months, but it usually is contained at the level of the regional lymph node and ultimately self-limited.

In contrast to CSD, *B. henselae* infection in an immunocompromised host presents a very different picture. Patients with AIDS cannot contain the infection at the level of the lymph node. Bacteria reach the general circulation, inducing persistent fevers and causing metastatic infection in the skin and internal organs. The same manifestations also occur with infection by *B. quintana* in AIDS patients. A notable feature of disseminated *Bartonella henselae* and *quintana* infection in the immunocompromised host is vascular proliferation at sites of local bacterial infection, a process named bacillary angiomatosis. Lesions teem with bacteria appearing in aggregates or microcolonies, and these bacteria have the capacity to induce small blood vessels to proliferate. The result is the development angioproliferative tumors in skin, other tissues, or organs. In addition, endothelial-lined blood-filled cysts in the liver may form in association with microcolonies of bacteria, a disease process known as bacillary peliosis. Vascular proliferation accounts for the warty appearance of verruga peruana (caused by *B. bacilliformis*) and the similar appearance of *B. henselae* or *B. quintana* bacillary angiomatosis lesions in patients with AIDS.

Occasionally, *Bartonella*, either in immunocompetent or immunocompromised hosts, cause localized infection of the eye (Parinaud's oculoglandular syndrome, a granulomatous conjunctivitis with accompanying lymphadenopathy; retinitis), heart valves (endocarditis) or brain (encephalitis; meningitis). *Bartonella* infection should always be considered in the differential of "culture negative" endocarditis, especially with the appropriate zoonotic exposures.

Diagnosis, Treatment, and Prevention

The *Bartonella* species are not obligate intracellular pathogens and can therefore very rarely be isolated on routine clinical laboratory culture media. However, although culture on standard blood agar plates is sometimes feasible, it is very insensitive and untimely. The development of colonies may take weeks of incubation. New insect cell culture-based medium holds promise in increasing recovery of organisms. However, because of the insensitivity of bacterial culture and unavailability of optimal culture medium in most diagnostics settings, almost all cases are diagnosed by serologic and/or molecular testing. Notably, serological tests are commonly available only for *B. henselae* and *quintana*. Therefore, zoonotic disease caused by other *Bartonella* species is certainly under-diagnosed. Studies in veterinarians for example suggest zoonotic exposure and infection by diverse *Bartonella* species.

Bartonella bacteria are susceptible to tetracyclines and macrolide antibiotics. Treatment of patients with BA or immunocompromised individuals is essential. However, in most cases of CSD, it is difficult to ascertain whether antimicrobial therapy has any beneficial effect on the duration or outcome of infection. There is no *Bartonella* vaccine for cat owners or their pets, but acquisition of the disease can be prevented by the treatment of pet cats and kittens for fleas and by avoidance of contacts that may break the skin or inoculate mucous membranes when handling these pets.

Conclusion

The two fastidious Gram-negative pathogens described in this article share elements of their basic structure and the potential to cause disease in humans. They are otherwise distinct in their preferred hosts and strategies for survival. Like many bacterial pathogens, these species cause particularly serious disease in impaired or immunocompromised hosts in whom the pathology may differ dramatically from that in healthy exposed individuals. Avoidance of infection by these species depend on public health measures, proper design and maintenance of water systems, and/or limiting zoonotic exposure especially for those at greatest risk for serious disease.

Glossary

Amastigote The aflagellated stage of *Leishmania*. Amastigotes are obligate intracellular parasites of mononuclear phagocytes of the vertebrate host.

Complement system A large number of small plasma proteins that act in concert, as part of the innate immune system of vertebrates. Complement actions include enhancing phagocytosis, inducing inflammation, and potentially effecting the lysis of microbes and some viruses.

Delayed-type hypersensitivity (DTH) reaction A cell-mediated immune reaction in the skin in response to foreign antigens, that is indicative of prior sensitization to those antigens.

Macrophage Large, actively phagocytic mononuclear cell that is found in tissues and blood.

Membrane attack complex (MAC) A large macromolecular complex of complement proteins that forms on foreign cell surfaces, creating a pore in the plasma membrane and leading to cell lysis.

Metacyclogenesis Developmental and biochemical transformation, occurring within the sand fly midgut, of the noninfectious procyclic promastigote into the highly infectious metacyclic promastigote.

Phagolysosome Organelle resulting from the fusion of a phagocytic vacuole with a lysosome.

Promastigote Flagellated insect stage of *Leishmania*. Promastigotes exist in the sand fly vector as either the replicative procyclic form (noninfectious) or the highly infectious (and nonreplicative) metacyclic form.

Reticuloendothelial system Part of the mammalian innate defense system, consisting of mononuclear phagocytic cells found in the lymph nodes, liver, spleen, and bone marrow.

Subclinical Infection without any overt clinical signs of disease.

Zoonotic disease An infectious disease in which the transmission cycle in nature is primarily within an animal population, and humans are only incidentally infected.

Abbreviations

CR	Complement receptor
DCL	Diffuse cutaneous leishmaniasis
DTH	Delayed-type hypersensitivity
ER	Endoplasmic reticulum
GPI	Phosphatidylinositol
IFN- γ	Interferon-gamma
IL	Interleukin
LCL	Localized cutaneous leishmaniasis
LPG	Lipophosphoglycan
MAC	Membrane attack complex
ML	Mucosal leishmaniasis
PFR	Paraflagellar rod
PPG	Proteophosphoglycan
TNF- α	Tumor necrosis factor-alpha
VL	Visceral leishmaniasis

Defining Statement

Leishmania are intracellular protozoan parasites of vertebrates that are transmitted by the bite of a sand fly vector. Their fascinating life cycle, cell biology, novel mechanisms of RNA processing and gene regulation are discussed. *Leishmania* are also an important model of intracellular parasitism and host–parasite immune interactions. The leishmaniasis are a diverse set of zoonotic diseases of

[☆]*Change History:* September 2014. PC Melby, BL Travi, and E Yaneth Osorio introduced small edits in the text of the article including citations, added the sections ‘Applications’ and ‘References,’ and added Figures and Table.

This article is an update of G.B. Ogden, P.C. Melby, *Leishmania*, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 663–673.

global importance, including diseases of the skin, mucosa, and a potentially fatal systemic disease; these are discussed along with current approaches to treatment and control.

Classification and Morphology

Leishmania are eukaryotic protozoan parasites of vertebrates in the family Trypanosomatidae (order Kinetoplastida). Characteristic of members of the order Kinetoplastida is the presence of a conspicuous Feulgen stain-positive (i.e., DNA-containing) kinetoplast (see 'Other membrane-bound organelles'). All members of the family Trypanosomatidae are parasitic for vertebrates or invertebrates and undergo morphological changes during transition between stages of their life cycle. Of the many genera in this family, only species of *Leishmania* and *Trypanosoma* are human pathogens. Two subgenera of *Leishmania*, *L.* (*Leishmania*) and *L.* (*Viannia*) are recognized, and 20 *Leishmania* species are pathogenic for humans.

Leishmania exist as morphologically distinct forms. In mammals, amastigotes are an obligate intracellular parasite of mononuclear phagocytes. The elongated motile promastigote form is found in female sand flies, which are the only known vectors for *Leishmania*. Promastigotes possess a single nucleus and are variable in length (15–25 μm) and shape (ellipsoid to slender). The most prominent features of stained promastigotes are the nucleus, the kinetoplast, and the flagellum (Figure 1); the kinetoplast and the origin of the flagellum define the anterior region of the parasite (see 'Flagellum'). Amastigotes are round in shape with a 2–10 μm diameter. This stage is aflagellar (i.e., the flagellum does not extend past the cell boundary), but the kinetoplast and nucleus remain visible in stained amastigotes.

Life Cycle and Ecology

Leishmania spp. have a complex life cycle (Figure 2) with two morphologically distinct forms, the amastigote (mammalian stage) and the promastigote (invertebrate stage) (Figure 1). The taxonomy of sand flies is complex and varies according to different authors. In the Old World the genera *Phlebotomus* and *Sergentomyia* are of medical importance and they include several species. In the New World *Lutzomyia* is the most important genus (Table 1). The female phlebotomine sand fly vector becomes infected during a blood meal when the fly bites (often repeatedly) an infected vertebrate host, creating a pocket of pooled blood. Upon drinking the bloodmeal, the fly ingests amastigotes, and within the blood meal itself, the amastigotes transform into the promastigote forms. These early stage promastigotes, termed procyclics, actively replicate within a chitin-containing gut lining (the peritrophic membrane) secreted by fly midgut epithelial cells (the members of the *Viannia* subgenus replicate in the hindgut, known as the pyloric triangle). About 3 days after being ingested by the fly, procyclic forms escape the peritrophic membrane and travel to the anterior portion of the midgut, where they attach to epithelial cells. This marks the early stage of metacyclogenesis, where procyclics transform into the nonreplicating, infectious, metacyclic promastigotes. Metacyclics are thinner and faster moving than procyclic forms, but more importantly, about 5 days after the bloodmeal, biochemical changes occur in the surface coat (see LPG in 'Plasma membrane and surface molecules'), which cause the release of metacyclics from midgut epithelial cells. The newly released, and now highly infectious, metacyclic promastigotes are free to migrate and attach to the stomodeal valve in the foregut. When sandflies attempt to feed on a new host to procure blood necessary for egg development these infectious promastigotes are egested into the wound. The accumulation of infective promastigotes in the stomodeal valve may create mechanical problems during feeding, forcing sand flies to probe in different skin sites, thereby introducing *Leishmania* promastigotes in multiple sites. Upon contaminating the wound of the vertebrate host, promastigotes are phagocytosed by tissue

Figure 1 Morphological characteristics of *Leishmania*. In (a) (including insert), the elongated forms of cultured *L. donovani* promastigotes are shown (stained with Giemsa, bar in insert = 10 μm). An arrow points to a kinetoplast (k) in the insert. (b) Shows the intracellular *L. donovani* amastigotes infecting hamster spleen cells after staining with Giemsa. Each of the darkly stained bodies within the cell's cytoplasm (arrow) is an amastigote. Photo of promastigotes kindly provided by Gary B. Ogden, amastigote photo by EYO.

Figure 2 Life cycle of *Leishmania*. *Leishmania* have two morphologically distinct forms, the amastigote and the promastigote. In this schematic diagram, transmission of the infectious promastigotes is shown to occur from the infected female phlebotomine sand fly vector to the two main reservoir animals (i.e., dogs or rodents). The infectious metacyclic promastigotes then infect mononuclear phagocytes in the animal reservoir and within the phagolysosome transform into non-motile amastigotes. The amastigotes replicate within the phagosome and eventually lyse the host cell. The cycle is completed when a sand fly ingests amastigotes from the reservoir during a blood meal. As is typical in zoonotic transmission, humans (frequently children) are incidentally infected; however, as indicated by the broken arrow, humans can (uncommonly) serve as reservoirs for the parasite (see full description of life cycle in 'Pathogenesis and host response').

phagocytic cells (neutrophils and macrophages) responding to the damaged tissue. Within the macrophage, promastigotes inhibit maturation of phagosome and rapidly transform into non-motile amastigotes. The amastigotes replicate within the acidic and hostile environment of the phagolysosome, eventually lysing the macrophage and releasing amastigotes to infect other macrophages. The cycle continues when a sand fly ingests free amastigotes or amastigote-infected macrophages during a blood meal.

The transmission of *Leishmania* in most endemic areas is maintained through a zoonotic cycle during which humans are only incidentally infected. In general, the species that cause cutaneous disease are maintained in small mammal reservoirs, whereas the domestic dog is the usual reservoir for the species that cause visceral disease. In most instances, multiple mammalian species are found to be infected with a given parasite, but usually there is a principal reservoir and the other animals are incidental hosts that play a secondary role in the transmission cycle. The transmission between reservoir and sand fly is highly adapted to the specific ecology of the endemic region. For instance, the reservoirs for *L. major* in the Middle East are desert rodents and the sand fly vectors cohabit the rodent burrows where they are protected from the extreme heat and low humidity of the desert environment. In the New World, the zoonotic cycle of parasites of the *Viannia* or *Leishmania* subgenus typically involves small mammals and sand flies that inhabit dense tropical and subtropical forests. Human infections occur when their activities bring them in contact with the zoonotic cycle. Anthroponotic transmission, where humans are the presumed reservoir, occurs with *L. tropica* in some urban areas of the Middle East and with *L. donovani* in India, Bangladesh and Nepal.

Cellular Biology

Plasma Membrane and Surface Molecules

Plasma membrane

Leishmania possess a bileaflet plasma membrane similar to the membranes of metazoan cells (i.e., multicelled eukaryotes). A membrane indistinguishable in appearance from the plasma membrane itself also surrounds the flagellum. During development of promastigotes these membranes undergo biochemical changes, which modulate parasite attachment to host tissues (see the following section). The plasma membrane that lines the flagellar pocket actively acquires nutrients by pinocytosis, and pinocytotic vesicles have been observed to travel to the cytoplasm, where they fuse with lysosomes. The flagellar pocket is also active in secretion by exocytosis.

Lipophosphoglycan

The entire surface of promastigotes, including the flagellum, is covered by a cell coat or glycocalyx composed predominantly of lipophosphoglycan (LPG), as well as lesser amounts of gp63 (see the following section), proteophosphoglycans (PPGs), and other

Table 1 Major species of *Leishmania* and their geographic distribution

molecules. LPG is anchored to the parasite via a phosphatidylinositol (GPI) linkage, as are most other surface molecules (including gp63 and PPGs). This type of lipid anchor is unusual in animal cells. In addition to the GPI lipid anchor, LPG has three other domains: a glycan core, repeats of a saccharide-phosphate region, and an oligosaccharide cap. The glycan core and lipid anchor are conserved among all species of *Leishmania*, whereas the carbohydrates in the repeat region and the cap are highly variable in composition.

Early in the development of *L. major* promastigotes in the sand fly, the terminal sugars of the LPG cap are predominantly galactose residues, but during metacyclogenesis these sugars are replaced by arabinopyranose. Because of these changes, procyclic promastigotes can attach to receptors on the epithelial layer of the sand fly midgut, allowing developing promastigotes to remain in the gut during digestion and excretion of the bloodmeal. Once the developmental transformation to the infectious metacyclic stage has taken place, changes in LPG composition enable the parasites to be released for passage to the sand fly's mouth parts to infect the next host. Similar events occur in other species of *Leishmania*, although the specific changes in LPG composition may differ. Certain species of sand fly are competent hosts for particular species of *Leishmania*. Variations in LPG structure, which accompany varying ability to attach to sand fly epithelial cells, seem to determine, at least in part, what species of sand fly are suitable hosts for a particular species of *Leishmania*. LPG also mediates protection against hydrolytic enzymes found in the digestive tract of the invertebrate host.

The creation of mutants unable to synthesize LPG, by targeted gene disruption, has helped to establish LPG's role in *L. major*'s virulence. LPG is thought to contribute to *L. major*'s virulence in key ways – providing resistance to oxidative damage in the

phagolysosome and protecting the parasite from the effects of human serum complement (LPG may not be needed for complement resistance in mice). Infective *L. donovani* or *L. major* metacyclic promastigotes possess a thickened cell coat because of an increase in the number of phosphorylated saccharides in the LPG. The LPG molecules in metacyclic promastigotes of *L. major* are almost double the length of those found in procyclics, long enough to prevent the membrane attack complex (MAC) of the complement system from reaching the plasma membrane and lysing the parasite. Noninfective procyclic promastigotes have a thinner LPG coat and are readily lysed by host complement; LPG is almost absent from amastigotes. Interestingly, *L. mexicana* LPG mutants behave differently, as they show little or no reduction in virulence in macrophages or in mice, demonstrating that *Leishmania* virulence factors may be species specific.

Attachment and entry of promastigotes into macrophages may require the interaction of several parasite surface molecules with macrophage receptors. Identification of the specific molecules required for uptake remains to be determined. LPG plays a role in the uptake of complement-opsonized parasites into macrophages; however, because LPG mutants are efficiently endocytosed by macrophages, LPG is not required for uptake (see the following section). The macrophage CR1 and CR3 surface complement receptors, which bind C3b and inactivated C3b (iC3b), respectively, mediate adhesion of the promastigotes to macrophages. Attachment via complement receptors does not trigger the oxidative burst during phagocytosis (the oxidative burst in the phagolysosome is required for efficient intracellular killing of *Leishmania*). Consistent with these observations, *in vitro* experiments with *L. major* have demonstrated the increased intracellular survival of complement-fixed metacyclic promastigotes in macrophages. LPG also transiently impairs phagosomal maturation and provides protection against degradation by lysosomal enzymes.

Glycoprotein 63

The major protein found on the surface of promastigotes in all pathogenic species of *Leishmania* is a 63-kDa phosphatidylinositol-linked glycoprotein designated gp63 (gp63 synthesis is downregulated in amastigotes). Biochemical and molecular analysis has identified gp63 as a type of zinc-dependent metalloprotease. Like LPG, the surface expression of gp63 is increased during metacyclogenesis. Surface exposure of gp63, however, is largely blocked by the elongated metacyclic LPG. Gp63 may play a secondary role in the binding of *Leishmania* to the macrophage surface and subsequent entry by receptor-mediated endocytosis. As C3b is converted to iC3b by gp63, it has been suggested that an accumulation of iC3b on the parasite's surface would promote phagocytosis by CR3; as mentioned earlier, this would prevent a triggering of a more destructive oxidative burst during phagocytosis. GP63 also promotes intracellular infection by degrading or altering the function of several macrophage signaling molecules, including kinases, transcription factors, and phosphatases.

Flagellum

The flagellum originates from the anterior of the cell, arising from an invaginated region termed the flagellar pocket, and pulls, rather than pushes, the promastigote. In addition to serving as a means of locomotion, electron microscopy reveals that the *Leishmania* flagellum sometimes functions as a tether, attaching the developing promastigotes to the tissues lining the midgut of the sand fly vector (see LPG in 'Plasma membrane and surface molecules'). In the mammalian host, the functional role of the flagellum is curtailed, as the flagellum in amastigotes does not extend beyond the flagellar pocket. The flagellum has the typical 9 + 2 axoneme structure of metazoan cells, possessing a cytoskeletal core or axoneme of nine microtubule doublets surrounding two unattached inner microtubules. In addition, there is a complex cytoskeletal structure running parallel to the axoneme, termed the paraflagellar rod (PFR). The PFR is unique to kinetoplastids, euglenoids, and some dinoflagellates. Little is known about the role of the PFR, but *Leishmania* with mutations in PFR proteins have reduced swimming velocity. The basal bodies at the base of the flagellum are structurally similar to centrioles found in animal cells.

Nucleus

The *Leishmania* nucleus is spherical or slightly ovoid in shape, with a diameter of approximately 1.5–2.5 μm . It is unusual in that the nuclear membrane remains intact during nuclear division. During division, the nucleus elongates and then constricts, splitting the nuclear membrane into two. Spindle microtubules are believed to elongate and push the dividing nucleus apart, but how the genetic material is partitioned is unknown. The nuclear membrane itself is typical in appearance, possessing a double unit membrane studded with 65–100 nm diameter nuclear pores. The nucleus contains chromatin, but the chromosomes do not condense or become visible during nuclear division.

Other Membrane-Bound Organelles

Mitochondrion and kinetoplast

A single mitochondrion is present and is functional in both the insect and mammalian forms of *Leishmania* (i.e., cyanide-sensitive respiration is found in both forms of the parasite). Within the mitochondrion is the kinetoplast, one of the defining morphological features of members of the order Kinetoplastida. This structure lies at the base of the flagellum, close to the basal bodies from which the flagellum arises, and is visible by light microscopy. The kinetoplast is a large rod-shaped assemblage of kinetoplast DNA (kDNA) located within the mitochondrion. The kDNA itself is unusual, as spreads of purified kDNA visualized under the electron microscope appear predominantly as thousands of 'minicircles' and a few 'maxicircles' catenated (i.e., interlocked) into a large DNA network. This contrasts sharply with the mitochondrial DNA found in metazoan cells, which typically exists as a single circle of DNA. Moreover, maxicircles encode the usual mitochondrial genes but pre-mRNA transcripts for these genes must be extensively

edited (by uridine insertion and deletion) to generate a translatable form of mRNA. The 'RNA editing' process is dependent upon guide RNAs (gRNAs) acting as templates for editing, and these gRNAs are encoded by the minicircles (see [RNA editing](#), 'mRNA processing').

Endoplasmic reticulum and Golgi apparatus

The endoplasmic reticulum (ER) is similar in appearance to that found in metazoan cells. It is contiguous with the outer nuclear envelope and may be rough (containing attached ribosomes) or smooth (lacking attached ribosomes) in appearance. Closely associated with the ER is the Golgi apparatus, which appears as flattened membranous structures frequently stacked at the base of the flagellar pocket (in addition to being a site of endocytosis, the flagellar pocket is active in exocytosis).

Molecular Biology and Control of Gene Expression

Genomic Organization

Recently, the genomes of several of the *Leishmania* (including *L. major*, *L. infantum*, *L. donovani*, *L. L. amazonensis*, and *L. V. braziliensis*) have been sequenced and analyzed. *Leishmania* spp. have 34–36 linear chromosomes, with each genome measuring about $3.0\text{--}3.8 \times 10^7$ nucleotides. This is approximately eight times the size of the genome of the bacterium *Escherichia coli*. The estimates for the number of putative protein-encoding genes found are very similar for the three species of *Leishmania* ranging from about 8000 to 8300 genes. Many of these genes are repeated multiple times in tandem, forming large gene clusters. About 50% of the genes identified have no known function; however, 3–4% of these genes encode leucine-rich repeat sequences that are thought to bind to complement receptor CR3. The *Leishmania* genomes have a high degree of synteny. Despite wide geographical distribution, unique ecological niches, and diverse clinical manifestations, more than 90% of the genes are shared among the different pathogenic species. There are remarkably few genes that are unique to a given species, although differences in gene copy number may impact the parasite-host interaction and disease expression. Notably, the genomes of the Old World species contain transposable elements and RNA interference machinery that is lacking in *L. braziliensis*. *Leishmania* spp. appear to be primarily asexual, however sexual crosses were recently discovered to occur in promastigotes within the invertebrate host prior to metacystogenesis. Analysis of multiple field isolates suggests a high level of endogamous sexual recombination that likely contributes to strain diversity within an endemic area.

mRNA Processing

RNA editing

Two of the most uncommon types of messenger RNA (mRNA) processing, namely, RNA editing and trans-splicing, were first discovered in studies on trypanosomatid protozoa. One of these, RNA editing, has changed our understanding of how gene expression may be controlled in eukaryotes. The kDNA maxicircles mentioned earlier encode genes for ribosomal RNA, and certain proteins necessary for oxidative phosphorylation and electron transport in the mitochondrion. The study of many of these genes revealed that the mature mRNA sequences are different from the genomic DNA sequence from which they are transcribed. Moreover, many of the genomic sequences do not code for a functional protein. These observations were reconciled when it was discovered that a posttranscriptional process, now termed RNA editing, resulted in the site-specific deletion or addition of uridine (U) residues in the mRNA, which created functional initiation sites for protein translation and/or created an open reading frame for protein translation. RNA editing, in effect, repairs 'defects' in certain protein-coding regions in the DNA at the RNA level, enabling the expression of a functional protein from the processed mRNA. gRNAs are known to be critically important to this process. The gRNAs carry the template for proper mRNA editing and may also contribute U residues to the editing process. It is not clear why the trypanosomatids rely on this unusual form of gene regulation.

Trans-splicing

It is believed that within any species of trypanosomatid protozoa all mature mRNAs possess an identical 5' exon sequence. This 5' sequence, termed the 'spliced leader' or 'mini-exon,' is encoded by a gene separate from the genes corresponding to the mRNA transcripts. The mechanism for linking the mini-exon to the mRNA, termed trans-splicing, was first discovered in *Trypanosoma brucei* and is now known to also occur in about 10–15% of nematode mRNAs and in some flatworm mRNAs. The biochemistry of trans-splicing is similar to conventional cis-splicing where one exon is fused to a second downstream exon by two sequential transesterification reactions, resulting in the covalent joining of the two exons and the excision of the intervening or 'intron' sequence (in the form of a partially circular molecule termed a 'lariat structure') from the precursor mRNA. Although both mechanisms use small nuclear RNA-protein complexes (i.e., snRNPs) in catalyzing this reaction, the crucial difference between cis- and trans-splicing is that the two exons linked in trans-splicing are not encoded on the same pre-mRNA molecule, but rather are transcribed from separate genes. As a consequence of splicing two separate transcripts, the trans-splicing reaction releases a branched or 'Y-shaped' intron instead of a lariat. In all *Leishmania* spp. studied, the spliced leader RNA is transcribed from clusters of tandemly repeated genes (ranging from about 90 to 200 copies) on the genome. In *L. enrietti*, an 85 nt spliced leader RNA is transcribed from a 440 bp long gene. At the 5' end of this transcript is the 35 nt mini-exon sequence found at the 5' end of all mature *L. enrietti* mRNAs.

Control of Gene Expression

For most eukaryotes and bacteria, gene expression is controlled primarily by regulating the initiation of transcription. In this paradigm, transcriptional promoters on the genome largely dictate where, and how often, initiation of transcription takes place. No RNA polymerase II promoter sequence has been clearly identified in any *Leishmania* spp. Transcription in *Leishmania* appears to be nonstringent, as promastigotes transfected with plasmids containing the gene for neomycin resistance (but containing no *Leishmania* sequences) were shown to actively transcribe the neomycin gene. All that was required was the incorporation of a signal for trans-splicing in the neomycin gene sequence. So far, other evidence for a true *Leishmania* promoter has been merely suggestive or inconclusive. Thus, gene regulation in *Leishmania* and other kinetoplastids depends largely on posttranscriptional mechanisms. Protein-coding genes are arranged in long head to tail tandem repeats and are transcribed as polycistronic mRNAs. These are converted to monocistrons by trans-splicing at the 5' end and polyadenylation at the 3' end. The polyadenylation of an upstream gene is functionally coupled to trans-splicing of a downstream gene. The formation of mature mRNA may then be controlled by regulating splicing and/or polyadenylation. Tandemly repeated genes may enable the cell to increase the expression of a protein (by increasing gene copy number) without modulating the initiation of transcription. Changes in the transcriptome, most evident during life cycle differentiation, are most heavily influenced by RNA stability. Trans-acting factors (RNA binding proteins) are thought to bind to the 5' or 3' ends to selectively stabilize or destabilize the mRNAs.

DNA Transfection and Gene Targeting

A major contribution to the molecular analysis of *Leishmania* was the development of functional plasmid expression vectors in 1990. Two groups used an *E. coli* plasmid in combination with the intergenic region of the α -tubulin gene or the flanking region of the *dhfr-ts* gene to construct a *Leishmania* plasmid. More recently, other plasmids have been made: several selectable markers are available for stable transfection (e.g., neomycin, hygromycin, bleomycin, and puromycin) and a number of phenotypic markers are available for transient assays (e.g., β -galactosidase, luciferase, and β -glucuronidase). Negative selection is also possible using the thymidine kinase gene. Important questions about the pathogenesis of *Leishmania* have been answered using these plasmids. As mentioned earlier, transfection of gp63-variant strains with gp63-expressing plasmids has helped to elucidate the role of gp63 in infection. Similarly, targeted mutations in LPG have contributed to our understanding of this molecule's role in virulence. Moreover, homologous recombination between a plasmid and the *Leishmania* genome has proved to be a powerful tool in studying the function of particular genes in these parasites. Researchers may now specifically target and eliminate the activity of a gene or add a gene to a species' genome. Although gene knockout experiments are potentially powerful in studying *Leishmania*, difficulties may arise, as many *Leishmania* genes are present in tandem repeats on the chromosome.

Pathogenesis and Host Response

The *Leishmania* parasite has multiple ways in which it adapts to, and survives within, both the invertebrate and vertebrate hosts. Within the sand fly, promastigotes undergo metacyclogenesis to the infective stage (see 'Life cycle and ecology'). When the sand fly takes a bloodmeal, the infective promastigotes are deposited in the host dermis to initiate the infection. Host factors (genetic background, concomitant disease, nutritional status), parasite factors (virulence, size of the inoculum) and possibly, vector-specific factors (sand fly genotype, immunomodulatory salivary constituents) influence the subsequent development and evolution of disease. As noted earlier (see 'Cellular biology'), the parasite's surface plays an important role in the entry and survival of *Leishmania* in the mammalian host cell by conferring complement resistance and by facilitating entry into dermal resident macrophages and dendritic cells without triggering a respiratory burst. As consequence of the infective insect bite, inflammatory mediators induced by the tissue trauma, complement C3, and/or components or microbiota in the sand fly saliva attract neutrophils that phagocytize the promastigotes. Neutrophils can kill the intraphagosomal parasite by fusion of myeloperoxidase-containing and tertiary granules, decreasing the intraphagosomal pH, and production of reactive oxygen radicals. When infected neutrophils become apoptotic they are phagocytosed by macrophages, which take on a tissue repair phenotype that is permissive to *Leishmania* infection. Inflammatory monocytes are recruited to the infection site by cytokines and chemokines released by neutrophils, platelets and fibroblasts. Recruited monocytes differentiate locally into monocyte-derived dendritic cells or into macrophages and facilitate the trafficking of parasites to the draining lymph node. The parasitized phagocytes may induce an adaptive immune response by presenting *Leishmania* antigen to lymph node T cells, or provide a permissive site for parasite replication, long-term survival and systemic spread.

There is extensive evidence from experimental animal models that adaptive cellular immune mechanisms mediate resistance to *Leishmania* infection. The knowledge of immunological mechanisms related to resistance and susceptibility are largely derived from experimental models and are summarized in Figure 3. Resistance to leishmanial infection is associated with the capacity of CD4⁺ T cells (Th1 subset) to generate interferon-gamma (IFN- γ) in response to the parasite. Tumor necrosis factor-alpha (TNF- α) may contribute to protective responses by augmenting IFN- γ -mediated macrophage activation. Interleukin (IL)-12, which stimulates T cells and NK cells to produce IFN- γ , promotes Th1 subset expansion, suppresses Th2 cells (IL-4), and plays a critical role in the

Figure 3 Immunopathogenesis of *Leishmania* infection. The balance between the Th1 and Th2 cell response and the effect on macrophage activation and parasite killing is shown schematically. Inhibitory effects are noted by a (–). When Th1 cells are activated by *Leishmania* antigens, IFN- γ is produced, which downregulates the Th2 response and promotes classical macrophage (M1) activation with nitric oxide production. TNF- α , produced by macrophages, synergizes with IFN- γ to induce macrophage activation and parasite killing. If *Leishmania* antigens induce a Th2 response with IL-4 and/or IL-10 production, the Th1 response is inhibited and the macrophage is activated through an alternative (M2) pathway, making it permissive for parasite replication. The infected macrophage itself may also produce IL-10 and TGF- β , which promote parasite survival by deactivating the macrophage.

generation of a protective immune response. The killing of intracellular *Leishmania* is mediated by the generation of reactive oxygen and nitrogen intermediates. The latter mechanism is dominant in rodent models of leishmaniasis, but it has a less prominent role in killing of *Leishmania* by human macrophages. IFN- γ also drives the expression of a large number of antimicrobial effector genes, though the roles of these genes in the antileishmanial defense are largely unknown. CD8 $^{+}$ T cells may contribute to protective response through cytotoxic activity and IFN- γ production, but IL-10-producing CD8 $^{+}$ T cells may be involved in immunosuppression and immunopathology.

Susceptibility to leishmanial infection and progression of disease is associated with the production of IL-4 and IL-10 by T cells, and IL-10 and TGF- β by infected macrophages (see Figure 3). IL-4 is a cross-regulatory cytokine that inhibits the expansion of the Th1 subset of T cells. IL-10 inhibits the production of cytokines by Th1 cells by suppression of accessory cell function and IL-12 production.

Infected macrophages have a diminished capacity to initiate and respond to an inflammatory response, thus providing a safe haven for the intracellular parasite. IL-10 and TGF- β are potent inhibitors of the antimicrobial activity of macrophages, and the expression of IL-10 mediates the persistence of parasites in the infected tissue. In addition to the production of deactivating cytokines, infection of the macrophage, especially in the presence of the type 2 cytokines (IL-4 and IL-13), can lead to an alternative activation phenotype characterized by blunted IFN- γ -mediated activation, low NO production, high arginase activity, increased production of prostaglandin E_2 , and a gene expression profile that includes increased expression of phagocytic receptors, IL-1 receptor antagonist, and certain chemokines. Infected macrophages may also inhibit antigen presentation to effector T cells and there may be expansion of regulatory T cell populations. Both CD4 $^{+}$ CD25 $^{+}$ Foxp3 $^{+}$ regulatory T cells and IL-10-producing CD4 $^{+}$ CD25 $^{-}$ Foxp3 $^{-}$ T cells have been shown to promote chronic disease. Direct parasite-induced disruption or activation of a number of signaling pathways within the macrophage also contributes to macrophage permissiveness to infection.

CD4 $^{+}$ and CD8 $^{+}$ regulatory T cells and Th17 cells may play roles in both protection and pathology. CD4 $^{+}$ CD25 $^{+}$ Foxp3 $^{+}$ regulatory T cells and IL-10-producing CD4 $^{+}$ CD25 $^{-}$ Foxp3 $^{-}$ T cells have been shown to promote chronic disease. Leishmania-specific subsets of T regulatory cells may control inflammation and participate in resolution of CL. Th17 cells, a type of pro-inflammatory CD4 $^{+}$ T cell, are associated with both protection and pathological tissue destruction mediated by recruitment of neutrophils. Macrophages secrete IL-27 to control development of the Th17 subset, and collaborate with IL-21 to induce regulatory T cells to produce IL-10.

The cytokine response in human leishmaniasis has a mixed phenotype, driven by both innate (dendritic cells, natural killer cells, macrophages) and adaptive (T cells, B cells) immune cells. Abundant pro-inflammatory cytokines and chemokines (IL-6, IL-1, IL-8, TNF- α , IFN- γ , IL-12, CXCL10) are secreted together with anti-inflammatory cytokines (IL-10, IL-4, IL-13, IL-27 and TGF- β) that attempt to control the infection and excessive inflammation. The anti-inflammatory mediators may block classical activation by IFN- γ and TNF- α and down regulate IL-12, MHCII and co-stimulatory molecules in macrophages and dendritic cells. This results in deficient antigen presentation and impaired acquired immune response. The balance of pro-inflammatory and anti-inflammatory signals largely determines the outcome of infection, tissue pathology and disease resolution.

Patients who develop localized cutaneous leishmaniasis (LCL, see following text) generally exhibit strong protective antileishmanial T cell (Th1) responses and spontaneously heal within 3–6 months. Failure to clear the parasite or resolve inflammation may lead to chronic non-healing lesions. Patients with mucosal leishmaniasis (ML, see ‘epidemiology and disease’) exhibit a hyper-responsive cellular immune reaction, with prominent Th17-mediated neutrophilic inflammation, which leads to the extensive tissue destruction. These patients appear to have ineffective counterregulatory mechanisms, such as impaired IL-10 responsiveness, that contributes to the excessive inflammation. Patients with active disseminated disease (diffuse cutaneous leishmaniasis (DCL) or visceral leishmaniasis (VL) see ‘epidemiology and disease’) demonstrate minimal or absent *Leishmania*-specific cellular immune responses and low expression of IFN- γ by T CD4+ cells at the site of pathology. In non-healing LCL or VL local T cell dysfunction may be due to depletion of L-arginine by expression of arginase in parasites and host myeloid cells. In contrast to the suppressed T cell responses, patients with VL display a polyclonal activation of B lymphocytes and high circulating pro-inflammatory cytokines characteristic of systemic inflammatory response syndrome and sepsis.

Epidemiology and Disease

The leishmaniasis are highly prevalent, estimated to affect more than 10 million people in endemic tropical and subtropical regions on all continents except Australia and Antarctica. Over the past decade, an increased number of cases have been reported throughout the world, either as new sporadic cases in endemic regions or new epidemic foci. It is estimated that the global annual incidence of visceral leishmaniasis ranges between 200 000 and 400 000 cases while cutaneous leishmaniasis affects approximately 690 000 to 1 200 000 persons each year. The disease has emerged in new foci because of the following factors: (1) movement of susceptible people into existing endemic areas, usually because of agro-industrial development, (2) migration of infected individuals to new eco-epidemiologically high-risk regions due to social conflicts, (3) an increase in the vector and/or reservoir populations because of agriculture development projects, (4) heightened anthroponotic transmission because of rapid urbanization in some foci, and (5) increased sand fly density because of scaled-back malaria vector control programs.

The different leishmaniasis are distinct in their etiology, epidemiology, transmission, and geographical distribution. These features are summarized in Table 1. With only rare exceptions, the *Leishmania* species that primarily cause cutaneous disease do not visceralize. Cutaneous leishmaniasis may be localized to one or a few skin ulcers, which occur at the site of the sand fly bite (LCL), or in rare instances the parasite may disseminate to involve large areas of skin (DCL). ML, an uncommon complication of LCL, is a destructive, disfiguring infection of the nasal and oropharyngeal mucosa. VL is the most serious form because there is progressive parasitism of the visceral reticuloendothelial organs (liver, spleen, and bone marrow).

In most instances, when *Leishmania* are transmitted to humans, the infection is controlled by the host response and overt disease does not develop. Field studies in endemic areas reveal people who have no history of disease often have evidence of infection by virtue of a positive leishmanin (delayed-type hypersensitivity, DTH) skin test. In most endemic areas, subclinical infection (no overt disease) occurs 5–10-fold more frequently than active disease. Epidemiological studies indicate that individuals with previous active cutaneous leishmaniasis or subclinical infection are usually immune to a subsequent clinical infection. Within endemic areas the prevalence of DTH skin test positivity (related to previous subclinical or clinical infection) increases with age and the incidence of clinical disease decreases with age, indicating that immunity is acquired in the population over time.

LCL (also called oriental sore) can affect individuals of any age but children are the primary victims in many endemic regions. It typically presents as one or a few raised or ulcerated lesions located on skin that is exposed to the sand fly bite, for example, the face and extremities. Cases of more than a 100 lesions have rarely occurred. The lesions develop at the site of the sand fly bite and increase in size and often ulcerate over the course of several weeks to months. The lesions remain localized to the skin and the patient generally has no systemic symptoms. In general, the lesions are painless unless they develop secondary bacterial infections. Lesions caused by *L. major* and *L. mexicana* usually heal spontaneously after 3–6 months leaving a depressed scar. Lesions on the ear pinna caused by *L. mexicana*, called Chiclero’s ulcer because they were common in chicle harvesters in Mexico and Central America, often follow a chronic, destructive course. In general, lesions caused by *L. (Viannia)* spp. tend to be larger and more chronic.

DCL is a rare form of leishmaniasis caused by organisms of the *L. mexicana* complex in the New World and *L. aethiopica* in the Old World. DCL manifests as nonulcerating skin lesions, which often involve large areas of skin and may resemble the lesions of leprosy. The face and extremities are most commonly involved. Dissemination of the parasite from the initial lesion usually takes place over several years. It is thought that an immunological defect underlies this severe form of cutaneous leishmaniasis.

ML (also called espundia in Latin America) is an uncommon but serious manifestation of leishmanial infection resulting from the spread of the parasite from the skin to the nasal or oropharyngeal mucosa. ML is usually caused by parasites in the *L. (Viannia)* complex. In individuals who have, or have had, untreated skin lesions caused by *L. (V.) braziliensis* the lifetime risk of developing ML is estimated at 2–10%. In patients infected with *L. (V.) panamensis* the lifetime risk is about 5%. Patients with ML most commonly have nasal mucosal involvement, which results in symptoms of nasal congestion, discharge, and recurrent nosebleeds. In severe cases over the course of several years, there is marked soft tissue, cartilage, and even bone destruction, which lead to visible deformity of the nose or mouth, perforation of the nasal septum, and even obstruction of the airways.

VL (also called kala azar) typically affects children less than 5 years of age in the New World and Mediterranean region (*L. infantum* = *L. chagasi*), and older children and young adults in Africa and Asia (*L. donovani*). After inoculation of the organism

into the skin by the sand fly, the child may have a completely asymptomatic infection (no clinical signs of disease), or 2–9 months later show signs of active VL. There is typically no lesion at the site of the sand fly bite. The classic clinical features of VL include high persistent fever, enlargement of the liver and spleen, and severe cachexia (weight loss and muscle wasting). There is loss of bone marrow function, so the leukocyte and erythrocyte counts fall. Malnutrition is a risk factor for the development and more rapid evolution of active VL. Without the institution of drug therapy death occurs in more than 90% of patients. VL has been increasingly recognized as an opportunistic infection associated with HIV infection. Most cases have occurred in southern Europe (Mediterranean basin) and Brazil. Although anti-retroviral therapy has decreased the incidence of co-infected VL cases there is potential for many more cases as the endemic regions for HIV and VL converge. Disease may result from reactivation of a long-standing subclinical infection.

Diagnosis, Treatment, and Control

A definitive diagnosis of leishmaniasis rests on the microscopic detection of amastigotes in tissue specimens, or isolation of the organism by culture (performed only in specialized laboratories). A positive culture enables speciation of the parasite (usually by isoenzyme analysis by a reference laboratory). Serological tests are useful for the diagnosis of VL because of the very high level of antileishmanial antibodies, but not for ML or LCL where the antibody response is minimal or highly variable. PCR-based diagnosis is being increasingly used in secondary and tertiary health facilities but is still unaffordable in many endemic areas of developing countries.

Specific antileishmanial therapy is not routinely needed for uncomplicated LCL caused by strains that have a high rate of self-healing (*L. major*, *L. mexicana*). Lesions that are extensive or located where a scar would result in disability or disfigurement should be treated. Cutaneous lesions suspected or known to be caused by members of the *Viannia* subgenus (New World) should be treated because of the low rate of spontaneous healing and the potential risk of developing mucosal disease. Likewise, patients with lesions caused by *L. tropica* (Old World), which are typically chronic and non-healing, should be treated. All patients with VL or ML should receive therapy.

The pentavalent antimony compounds (sodium stibogluconate and meglumine antimoniate) have been the mainstay of antileishmanial chemotherapy for more than 40 years. These drugs are difficult to administer and have moderate toxicity. Using the recommended regimen, cure rates of 80–100% for LCL, 50–70% for ML, and 80–100% for VL can be expected. Failure of antimony therapy is more common in some parts of the world, and is particularly problematic in young children. Relapses are common in patients who do not have an effective antileishmanial cellular immune response, such as patients who have DCL or are co-infected with HIV. These patients often require multiple courses of therapy. Several alternative therapies have been used in the treatment of the leishmaniasis, including the antifungal agent Amphotericin B and its related lipid-associated compounds, parenteral paromomycin (aminosidine) and pentamidine. Recently, single doses of Amphotericin B in a liposomal formulation was demonstrated to be effective in treating visceral leishmaniasis in India. Recombinant human IFN- γ has been successfully used as an adjunct to antimony therapy in treatment of refractory cases of ML and VL. Oral miltefosine has been used with success in treating VL in India and is currently used as second line treatment for cutaneous leishmaniasis in the Americas. The development of significant resistance may be a problem with miltefosine. The oral antifungal drugs ketoconazole and fluconazole have been effective in treating some patients with LCL. Topical cream formulated with paromomycin–gentamicin achieved cures rates >80% in patients infected with *L. major*. This formulation also has been proposed as an alternative for treating New World CL.

Leishmaniasis is best prevented by avoiding exposure to sandflies and use of insect repellents. Where transmission is occurring near homes, community-based insecticide (deltamethrin) spraying indoors or utilization of insecticide-impregnated bednets has had some success in reducing human infections. Control or elimination of infected reservoir hosts (e.g., seropositive domestic dogs) has had limited success. Where anthroponotic transmission is thought to occur, the early recognition and treatment of cases is essential. Because humans acquire long-standing immunity following infection with *Leishmania*, prevention of the disease through vaccination is a possible approach. No vaccines for humans are currently available but immunization studies involving experimental animal models are promising. Vaccination of humans, or domestic dogs to prevent transmission of VL, may have a role in the prevention of leishmaniasis in the future.

Glossary

Acyl carrier protein (ACP) Low molecular weight cytosolic protein functioning as the acyl group carrier for all the intermediates in fatty acid biosynthesis.

Bacillus subtilis The most intensively characterized Gram-positive bacterium.

Escherichia coli Paradigmatic Gram-negative bacterium that has been used for the vast majority of work on bacterial lipid metabolism.

Fatty acids Carboxylic acids with a long aliphatic carbon chain. Carbon atoms of fatty acids are numbered starting at the C-terminus. The position of the double bond in unsaturated fatty acids is represented by the symbol Δ followed by a superscript number. For example, cis- Δ^9 means that there is a cis double bond between carbon atoms 9 and 10.

Phospholipid Major constituents of biological membranes, composed of two fatty acids, esterified to the first two positions of a glycerol backbone, and a polar headgroup attached to the third position via a phosphodiester bond.

Abbreviations

ACC	acetyl-CoA carboxylase
ACP	acyl carrier protein
acyl-CoA	acyl-coenzyme A
CDAGS	CDP-diacylglycerol synthetase
CFA	cyclopropane fatty acid
CL	cardiolipin
CLS	CL synthase
Cti	cis-trans isomerase
DHAP	dihydroxyacetone phosphate
FASII	type II fatty acid synthase
G3P	glycerol-3-phosphate
G3PD	glycerol-3-phosphate dehydrogenase
LPA	lysophosphatidic acid
PA	phosphatidic acid
PAP	phosphatidic acid phosphatase
PC	phosphatidylcholine
Pcs	phosphatidylcholine synthase
PE	phosphatidylethanolamine
PG	phosphatidylglycerol
PGP	phosphatidylglycerol phosphate
PGPP	PGP phosphatase
PGPS	PGP synthase
PS	phosphatidylserine
PSD	phosphatidylserine decarboxylase
PSS	PS synthase
SAM	S-adenosylmethionine
SFA	saturated fatty acid
UFA	unsaturated fatty acid
UGT	UDP-glucosyltransferase

[☆]Change History: August 2014. D de Mendoza and GE Schujman introduced small edits in the text of the article, updated further readings, added the section "Engineering of Fatty Acid Biosynthesis for biofuel production", and added new Figure 5.

This article is a reprint of D. de Mendoza, G.E. Schujman, Lipid Biosynthesis, *Reference Module in Biomedical Sciences*, Elsevier, 2014.

Defining Statement

Lipids are important components of the plasma membrane of all bacteria and play a key role in cell viability. The major membrane lipids are phospholipids consisting of fatty acids esterified to glycerolphosphate derivatives and are called phosphoglycerides. Biochemical, genetic, and structural studies permitted to understand in great detail the phosphoglyceride metabolism in model bacteria.

The Type II Fatty Acid Biosynthetic Pathway

Fatty acid synthesis is essential for the formation of membranes and hence for the viability of all cells except Archaea, in which the membranes are composed of glycerol-ether lipids instead of glycerol-ester lipids and are based on isoprenoid side chains.

Fatty acid synthesis in bacteria is achieved by a highly conserved set of genes that each encodes an individual step in the type II fatty acid biosynthetic pathway (FASII) (Figure 1). Each protein of the pathway is located in the cytosol, and reaction intermediates are covalently attached to acyl carrier protein (ACP). The ACPs are a group of highly related small acidic proteins with molecular weights of about 9.0 kDa. The acyl intermediates of fatty acid biosynthesis are bound to ACP through a thioester linkage attached to the terminal sulfhydryl of the 4'-phosphopantetheine prosthetic group.

Malonyl-CoA is required for all the elongation steps of the fatty acid biosynthetic pathway and is formed by carboxylation of acetyl-CoA by acetyl-CoA carboxylase (ACC). ACC is constructed from four separate proteins and requires biotin as a cofactor. Malonyl-CoA is made available to the enzymes of fatty acid biosynthesis by its conversion to malonyl-ACP by malonyl transacylase

Figure 1 Initiation and elongation cycle of fatty acid biosynthesis. Malonyl-CoA, the product of the acetyl-CoA carboxylase (ACC) reaction, is converted to malonyl-ACP by malonyl-CoA transacylase (FabD). The following step is catalyzed by β-ketoacyl ACP synthase III (FabH), which is able to utilize short acyl-CoA primers as substrates. The elongation of the growing acyl chains is accomplished in four successive steps catalyzed by the following enzymes: β-ketoacyl ACP synthase I or II (FabB or FabF, respectively), β-ketoacyl ACP reductase (FabG), β-hydroxyacyl-ACP dehydrase (FabZ), and enoyl reductase (FabI).

(FabD). The chain elongation step in fatty acid biosynthesis consists of the condensation of acyl groups, which are derived from acyl-ACP or acyl-coenzyme A (acyl-CoA), with malonyl-ACP by the β -ketoacyl-ACP synthases (often referred as condensing enzymes). These enzymes are divided into two groups. The FabH class of condensing enzymes is responsible for the initiation of fatty acid elongation and utilizes acyl-CoA primers. *Escherichia coli* produces straight chain and unsaturated fatty acids (UFA), and *E. coli* FabH selectively uses acetyl-CoA to initiate the pathway. In contrast, *Bacillus subtilis* produces mainly branched-chain fatty acids and contains two FabH isozymes (named FabHA and FabHB) that differ from the *E. coli* enzyme in that they are selective for branched-chain acyl-CoAs. The FabF–FabB class of condensing enzymes is responsible for the subsequent rounds of fatty acid elongation in the pathway. These enzymes condense malonyl-ACP with acyl-ACP to extend the acyl chain by two carbons. The FabF isoform is universally expressed in bacteria, and in *B. subtilis* is the sole condensing enzyme able to carry out the subsequent elongation reactions in fatty acid synthesis. *E. coli*, and some other bacteria, also have the FabB isoform, which plays a special role in the synthesis of UFA (see ‘Biosynthesis of UFAs’). FabG is the β -ketoacyl-ACP reductase and only a single isoform of this enzyme has been identified so far in bacteria. The next step in the elongation cycle is the dehydration of β -hydroxyacyl-ACP to *trans*-2-enoyl-ACP. Two isoforms, FabZ and FabA, catalyze the dehydration of β -hydroxyacyl-ACPs, albeit with different substrate specificities. FabZ is universally expressed in bacteria, whereas FabA is restricted to organisms that use the FabA/B system to introduce double bonds into the growing acyl chain (see ‘Biosynthesis of UFAs’). Although most FAS II enzymes are relatively conserved in bacteria, an exception is the last step of the elongation cycle, where a saturated acyl-ACP is formed by a NAD(P)H-dependent reduction of the enoyl-ACP double bond. In *E. coli*, this reaction is catalyzed by FabI, while *B. subtilis* contains two isozymes, a FabI homologue and FabL that, like FabI, is a member of the short chain reductase superfamily. *Vibrio cholerae* contains FabV, a NADH-dependent member of the short chain reductase superfamily, while *Streptococcus pneumoniae* contains a single enoyl reductase, FabK, unrelated to this last superfamily of enzymes.

E. coli and mostly of Gram-negative bacteria synthesize straight-chain fatty acids, but there can be a major variation of this paradigm. Branched-chain fatty acids are produced in several Gram-positive bacteria, such as *Bacillus*, *Streptomyces*, and *Listeria*, and exist in two forms that are characterized by the presence of either iso and anteiso branches at their termini. The primer carbons for the synthesis of branched-chain fatty acids are 2-ketoacids derived from valine, leucine, and isoleucine. While isoleucine is the precursor of anteiso-branched-chain fatty acids, leucine and valine give rise to the primers for iso-branched chain fatty acids. The enzyme responsible for the formation of the branched-chain acyl-CoAs is a specialized branched-chain α -ketoacid dehydrogenase complex. These branched-chain acyl-CoAs are then introduced into the FASII pathway by FabH enzymes of the appropriate substrate specificity.

Biosynthesis of UFAs

Bacterial growth requires an appreciable fraction of acyl chains of the membrane lipids to be in a disordered state (fluid). A disordered state is imparted by presence of either *cis*-unsaturated or terminally anteiso-branched-chain fatty acids both of which act to offset the closely packed ordered arrangement of the lipid bilayer acyl chains that is imparted by straight chain saturated acyl chain. In this section, we discuss the basic features of biosynthesis of UFA in organisms in which the proposed biosynthetic mechanisms have been well characterized. In *E. coli*, synthesis of the normal UFA content requires three enzymes, FabA, FabB, and FabF (Figure 2(a)). FabA, β -hydroxydecanoyldehydrase, is the key enzyme of the classic anaerobic pathway of UFA synthesis and introduces a *cis* double bond into a 10-carbon intermediate. FabA is a bifunctional enzyme that catalyzes both the removal of water to generate *trans*-2-decenoyl-ACP and the isomerization of this intermediate to *cis*-3-decenoyl-ACP. This *cis*-10 carbon intermediate is then elongated by FabB and later by FabF to form the two major UFA found in *E. coli*: C16:1 Δ^9 and C18:1 Δ^9 . FabB and FabF have distinct and nonoverlapping roles in *E. coli* UFA synthesis. FabB is thought to elongate the product of the FabA enzyme to the C12 unsaturated intermediate, whereas FabF is required to convert C16 unsaturated species to the C18 species (Figure 2(a)).

Expression of the key UFA synthetic gene *fabA* from *E. coli* is positively regulated by FadR which was hitherto thought to function only as a repressor of the β -oxidation pathway of fatty acids (see ‘Fatty Acid β -Oxidation’). Positive regulation of *fabA* expression is neutralized both *in vivo* and *in vitro* by long-chain acyl-CoAs that are small ligands which regulate the binding of FadR to the *fabA* promoter. FadR is also a positive regulator of *fabB*, the second UFA biosynthetic gene, although the changes in *fabB* expression in *fadR* mutants are not as great as with *fabA*. Thus, FadR acts as a repressor of β -oxidation genes and as an activator of the two genes required for UFA synthesis. FabR is a second *E. coli* regulator of UFAs synthesis. It behaves as a repressor acting downstream of FadR operator in the regulation of *fabA* and *fabB*. The ligand regulating FabR activity is still unknown.

There is a variation of the FabA/FabB bacterial strategy for UFA synthesis, discovered in *Enterococcus faecalis*. This organism possesses a special FabZ enzyme (called FabN) that has a FabA-like activity and a unique FabF (called FabO) that replaces FabB. However, other organisms, such as *S. pneumoniae*, compensate FabA absence with an enzyme called FabM that is capable of isomerizing the *trans*-unsaturated bond at the key 10-carbon intermediate to its *cis*-isomer.

In the examples mentioned above, the proteins FabA, FabM, or FabN anaerobically introduce the double bond into a C10 intermediate and either FabB or FabF, in the organisms lacking FabB, channel this intermediate to the mainstream of the fatty acid synthetic pathway. In contrast, other bacteria like *Bacillus* and Cyanobacteria have completely separate systems for the synthesis of UFA and saturated fatty acids. These organisms use fatty acid desaturase enzymes, which require molecular oxygen and reducing equivalents obtained from an electron transport chain, to introduce the double bond into previously synthesized saturated fatty acids (Figure 2(b)).

Figure 2 Unsaturated fatty acid (UFA) biosynthesis and modification. (a) In *Escherichia coli* and related bacteria, FabA catalyzes the key step in UFA production, introducing the double bond into the acyl chain at the 10-carbon intermediate. FabA is a bifunctional enzyme that catalyzes both the removal of water to generate *trans*-2-decenoyl-ACP and the isomerization of this intermediate to *cis*-3-decenoyl-ACP. The FabB enzyme is required for the elongation of these unsaturated acyl-ACP intermediates, and FabF participates in SFA synthesis and in the elongation of C16:1 Δ 9 palmitoleoyl-ACP to C18:1 Δ 11 *cis*-vaccenoyl-ACP. The reactivity of this enzyme toward C16:1 Δ 9 palmitoleoyl-ACP is increased after a temperature downshift. (b) Reactants and products of a representative fatty acid desaturase reaction. This is a $2e^-$ - and O_2 -dependent dehydrogenation at an unactivated position of the fatty acyl chain, resulting in *cis*-double-bond formation. (c) Modification of the acyl-chain double bonds of bacterial lipids. The *cis* acyl-chain double bond can be isomerized to a *trans* acyl-chain double bond or methylated to form a cyclopropane ring. The configuration of the double bond is conserved in the cyclopropanation reaction. SAH, S-adenosylhomocysteine; SAM, S-adenosylmethionine.

The organisms mentioned above each have only a single pathway for the synthesis of the UFAs required to make functional membrane lipids. In marked contrast, UFA biosynthesis in *Pseudomonas aeruginosa* proceeds by three distinct pathways. In this organism, the FabA–FabB pathway does the bulk of UFA synthesis under all growth conditions. However, *P. aeruginosa* has two fatty acyl desaturases (DesA and DesB) that supplement the FabA–FabB pathway under aerobic conditions and thereby allows faster

growth. DesA introduces the double bond into the acyl chains of intact phospholipids, whereas the substrates of DesB are acyl-CoAs that are derived from exogenous fatty acids. DesB is inducible and is regulated by DesT, a transcriptional regulator that has the property of being able to sense the fatty acid composition of the long chain acyl-CoA pools to adjust the expression of the desaturase.

Phospholipid Synthetic Pathways and Headgroup Diversity

The type and proportion of each complex lipid vary greatly according to the bacterial genus. In the model organisms, *B. subtilis* and *E. coli*, the phospholipids consist largely of the common bacterial lipids phosphatidylethanolamine (PE) and phosphatidylglycerol (PG), while in *B. subtilis* almost 30% of membrane lipids are composed of the glycolipids, mono-, di-, and triglycosyldiacylglycerols, absent in *E. coli*. The Gram-negative bacterium contains important amounts of cardiolipin (CL), which is only minor in *B. subtilis*.

In all organisms, phospholipid biosynthesis begins with two acylation steps of *sn*-glycerol-3-P (G3P) to form phosphatidic acid (PA) (Figure 3). The synthesis of G3P from dihydroxyacetone phosphate (DHAP) is catalyzed by GpsA (G3P dehydrogenase [NAD⁺]), and similar proteins are encoded in a wide diversity of bacterial species. Therefore, the GpsA reaction likely provides the phospholipid 'backbone' of most bacteria. Two pathways have been described for the first acylation of G3P. The most ubiquitous one, present in all but one family of proteobacteria, involves two biochemical steps: first, PlsX catalyzes the synthesis of fatty-acyl-phosphate from acyl-ACP and inorganic phosphate and then the acyltransferase PlsY transfers the fatty acid from the activated acyl intermediate to the 1-position of G3P. In the second pathway, present in the γ -proteobacteria, the acyltransferase PlsB catalyzes the acylation of G3P to give lysophosphatidic acid (LPA). This enzyme utilizes either long-chain acyl-ACP or acyl-CoA as the acyl-donor.

Figure 3 Initiation of phospholipid biosynthesis in bacteria. Glycerol-3-phosphate (G3P) is synthesized by the product of the *gpsA* gene, glycerol-3-phosphate dehydrogenase (G3PD). In *Escherichia coli* and related bacteria, PlsB catalyzes the formation of 1-acylglycerol 3-phosphate (lysophosphatidic acid (LPA)) from glycerol 3-phosphate (G3P) and acyl-ACP (or acyl-CoA). In most bacteria, two enzymes replace PlsB activity: first, PlsX catalyzes the synthesis of fatty acyl-phosphate from acyl-ACP; second, PlsY transfers the fatty acid from the activated acyl intermediate to the 1-position of G3P. LPA is then acylated to phosphatidic acid by PlsC.

Acylation of 2-position of LPA to give phosphatidic acid is carried out by PlsC (Figure 3). PlsB, PlsC, and PlsY are intrinsic membrane proteins, while PlsX is a soluble enzyme that *in vivo* is anchored to the membrane by a still unknown mechanism.

Most sequenced bacterial genomes encode a protein having strong homology to CDP-diglyceride synthase, the *E. coli* enzyme encoded by the *csdA* gene. This enzyme catalyzes the conversion of PA to the activated intermediate, CDP-diglyceride, which can then be utilized in the synthesis of either PE or PG and CL. These two branches of the pathway present different pictures. The enzymes of the pathway to PE, the major phospholipid of *E. coli* and many other bacteria, are semiconserved. The first enzyme of the *E. coli* pathway, phosphatidylserine synthase (PssA), is poorly conserved outside of the alpha and gamma proteobacteria, whereas protein homologous to the second enzyme, phosphatidylserine decarboxylase (Psd) is widely distributed among bacteria. In contrast to *Bacillus* spp. where PssA is a membrane-associated protein, the PssA from *E. coli* is a soluble protein that is able to associate to the membrane (Figure 4).

The other branch of the pathway, which leads to PG and CL, begins with the *pgsA*-encoded-CDP-diacylglycerol-G3P 3-phosphatidyltransferase, which, like GpsA and Cds, is widely conserved. The next step in the pathway, removal of the phosphate moiety from PG phosphate, is indeterminate because at least three different enzymes (PgpA, PgpB, and an unknown protein) are thought to catalyze this hydrolytic step. The condensation of two molecules of PG to give CL and glycerol is catalyzed in *E. coli* by the *cls* gene product, CL synthase (Figure 4). Like *pgsA*, this gene is widely conserved. It seems that PG, but not CL, is essential for viability of *B. subtilis*. This situation is similar to that in *E. coli* where PG has important physiological roles in various cellular processes, such as initiation of DNA replication and protein secretion.

A variation of the biosynthetic pathways detailed above is the formation of glycolipids by the reaction of a UDP-sugar with diacylglycerol. Glucosyl- and diglycosyl-diacylglycerol are abundant lipids in many Gram-positive bacteria, and these lipids function as membrane anchors for the lipoteichoic acid constituents of the cell wall. For instance, the *ypfP* gene of *B. subtilis* codes for a UDP-glucosyltransferase (UGT), which catalyzes the addition of glucose residues to 1,2-diacylglycerol (Figure 4). The enzyme is able to sequentially add up to four glucose residues to 1,2-diacylglycerol, but *in vivo* the diglucosylacylglycerol is the main glycolipid found. This enzyme is specific for the sugar donor and acceptor and appears to be bound to membrane. In addition to glycolipids, there are membrane components that are not phospholipids. For example, sulfolipids and ornithine-derived lipids are produced by some bacteria when phosphorous availability is scarce.

Phosphatidylcholine (PC) is the major phospholipid in eukaryotes where it fulfills important structural and signaling functions. In contrast, only about 10% of all bacterial species are predicted to produce PC. It is notable that many of these bacteria are either symbionts or pathogens of animals and plant hosts. However, the advantage of having PC in their envelope, presumably in the inner and outer membrane, is unclear. PC in bacteria can be synthesized via two alternative routes. A pathway unique to bacteria comprises the direct condensation of choline and CDP-diacylglycerol catalyzed by a phosphatidylcholine synthase (Pcs). In the methylation pathway, PC is produced by the threefold methylation of PE by one or more phospholipid *N*-methyltransferases using *S*-adenosylmethionine (SAM) as methyl donor.

Phospholipid Modifications in Bacteria

The acyl chains of bacterial membrane phospholipids are often altered after synthesis and incorporation into membrane lipid bilayers. All the three major acyl chain modifications involve double bonds (Figures 2(b) and 2(c)). In cyclopropane fatty acid (CFA) synthesis, a methylene carbon is added across the double bond to form a three-membered ring. In *cis-trans* isomerization, the double bond is reconfigured and, as discussed above, in desaturation a double bond is introduced into a saturated acyl chain.

Double bonds exist in two diastereoisomers: *cis* in which the two hydrogen atoms are located on the same side of the bond and *trans* in which the hydrogen atoms are on opposite sides of the bond. Both isomers kink the acyl chains in which they reside, although the kink of the *cis* isomer is much larger. Therefore, the *trans*-UFA mimics the physical properties of phospholipids that contain saturated fatty acid (SFA). Virtually all the double bonds in naturally occurring fatty acids are *cis* isomers, although the occurrence of *trans* fatty acids is well documented in a restricted number of bacteria, such as pseudomonads, vibrios, and methyltrophs. The *cis-trans* isomerization reaction leads to membranes that have higher phase transition, increased rigidity, and decreased permeability to solutes. Although this consideration argues that *cis-trans* isomerization is a mechanism to adapt the membranes to higher temperatures, most work has been made in *Pseudomonas putida*, an organism of interest for detoxification of soils and waters contaminated with organic solvents. The synthesis of *trans* fatty acid by *P. putida* has been interpreted as a mechanism to decrease penetration of solvents through the inner membrane. In this bacterium, it has been demonstrated that the *cis-trans* isomerization reaction is carried out by a periplasmic, haem-containing *cis-trans* isomerase (Cti).

In contrast to *cis-trans* isomerization, cyclopropanation is very widely distributed among bacteria. Unlike Cti, CFA synthase is a cytosolic enzyme, as expected from its dependence of the methyl donor SAM. The cyclopropane bond retains the *cis* double bond configuration of the acyl chain, and therefore phospholipids that contain CFAs have similar biophysical properties to those that are composed of *cis* UFA. However, the cyclopropane bond is more stable than a double bond and is physiologically useful, for example, cyclopropanation increases *E. coli* resistance to acid stress. In addition, the inactivation of a homologue of the *E. coli* *cfa* gene in *Mycobacterium tuberculosis*, in which a cyclopropane ring is normally introduced into mycolates, results in *M. tuberculosis* being unable to establish a persistent infection, which indicates that CFAs have an important role in the survival of bacterial pathogens.

Figure 4 Complex lipid biosynthesis. The first step is the activation of phosphatidic acid to CDP-diacylglycerol by CDP-diacylglycerol synthetase (CDAGS). Biosynthesis of phosphatidylethanolamine (PE) is achieved by the sequential catalysis of phosphatidylserine synthase (PssA) followed by phosphatidylserine decarboxylase (PSD). PG is formed by the condensation of CDP-diacylglycerol with G3P, catalyzed by PGP synthase (PGPS), followed by removal of the phosphate by PGP phosphatase (PGPP). CL is formed by the condensation of two molecules of PG catalyzed by the CL synthase (CLS). Diacylglyceride is synthesized by dephosphorylation of phosphatidic acid by phosphatidic acid phosphatase (PAP). The diacylglyceride is then glucosylated by one or two transfers of glucose from UDP-glucose in a sequential reaction catalyzed by UDP-glucosyltransferase (UGT).

Control of Fatty Acid Biosynthesis

Fatty acid synthesis is coordinately regulated with phospholipid, macromolecular synthesis, and growth as part of the response to changes in the environment. This control is crucial for membrane homeostasis, because the biophysical properties of membranes are determined in large part by the composition that results from *de novo* lipid biosynthesis. Many of these processes are rapid responses of the integrated biochemical network and do not involve changes in gene expression. An important recent development is the identification and characterization of transcription factors that globally coordinate the expression level of genes that function in lipid biosynthesis.

Biochemical Control of FASII

In *E. coli*, the long chain acyl-ACP end products have emerged as important negative effectors of the activity of FASII. The importance of long-chain acyl-ACP regulation was determined through the demonstration that acyl-ACP hydrolysis by thioesterases leads to dysregulated fatty acid biosynthesis and to the release of fatty acids into the medium. The enzymes that are inhibited *in vitro* by acyl-ACPs are ACC, the enzyme that catalyzes the conversion of acetyl-CoA to malonyl-CoA, FabH that catalyzes the first step of the pathway, and FabI that catalyzes the completion of acyl-ACPs elongation (Figure 1).

Recent evidence showed that PlsX, the peripheral enzyme that catalyzes the first committed step in the biosynthesis of phospholipids in *B. subtilis*, plays an important role in the coordination of the production of fatty acids and phospholipids. In this organism, the inactivation of PlsX leads to the cessation of both fatty acid and phospholipid synthesis. The inhibition of total lipid synthesis in PlsX-depleted cells was attributed to the accumulation of acyl-ACPs due to the block in its conversion to acyl-phosphate. This observation suggests that acyl-ACP may play a regulatory role in *B. subtilis* similar to acyl-ACP regulation of FabH and ACC in *E. coli*.

Transcriptional Control of FASII

A major advance in our understanding of the transcriptional control of bacterial lipid synthesis occurred following the identification of FapR, a global transcriptional repressor that controls the expression of the *fap* regulon involved in the biosynthesis of fatty acids and phospholipids in *B. subtilis*. The binding of FapR to its DNA targets is specifically inhibited by malonyl-CoA, an essential intermediate of fatty acid synthesis in all living cells, the cellular pools of which provide a mechanism for sensing the status of fatty acid biosynthesis and for adjusting the *fap* regulon accordingly. FapR is highly conserved in many Gram-positive organisms, many of which are human pathogens, including *Bacillus anthracis*, *Bacillus cereus*, *Listeria monocytogenes*, and *Staphylococcus aureus*. The consensus binding sequence of FapR is also highly conserved in the putative promoter regions of the *fapR* gene in these species. These observations indicate that the regulation mechanism observed in *B. subtilis* is probably conserved in many other organisms.

The recent crystal structure of the effector binding domain of FapR, alone and complexed with malonyl-CoA, has provided the first insight into the ligand-induced transcriptional regulation of fatty acid and phospholipid synthesis. FapR is a homodimeric protein that displays the typical 'hot-dog' fold characteristic of the thioesterase enzyme family. Binding of malonyl-CoA promotes an order-disorder transition, which transforms an open ligand-binding groove into a long tunnel occupied by the effector molecule in the complex. This ligand-induced modification propagates to the helix-turn-helix motifs, impairing their productive association for DNA binding. It was recently reported the structural characterization of full-length FapR from *Staphylococcus aureus* (SaFapR), a major Gram-positive pathogen causing several human infections. The crystal structures of SaFapR have been obtained from the protein alone and for the complexes with cognate DNA and malonyl-CoA. Structure based mutations that disrupt the SaFapR interaction is lethal for *S. aureus* suggesting that this homeostatic signaling pathway is a promising target for novel chemotherapeutic agents against Gram-positive pathogens (see 'Antibacterial Agents that Target Fatty Acid Biosynthesis').

The second global regulator, FabT, was identified in the human pathogen *S. pneumoniae*. In this bacterium, the 12 genes required for fatty acid biosynthesis are located together in a single cluster. The second gene in the cluster encodes the FabT transcriptional repressor, which regulates all these genes except *fabM* (involved in UFA biosynthesis, see 'Biosynthesis of UFAs'). A similar genetic organization is found in other Gram-positive bacteria, such as *Enterococcus*, *Clostridium*, and *Lactococcus*. The ligand that enhances FabT binding to DNA is long-chain acyl-ACP. Upon binding to acyl-ACP, the affinity of FabT for the DNA binding site is significantly increased and the FabT-acyl-ACP complex docks on the DNA and represses transcription of the FAS cluster. *B. subtilis* lacking FapR and *S. pneumoniae* deficient in FabT do not produce increased quantities of lipid, despite overexpression of the pathway enzymes. This observation strongly argues for the presence of biochemical regulatory mechanisms in both organisms that override transcriptional control to prevent excess production of phospholipids and maintain the appropriate lipid:protein ratio in the membrane.

Control of Membrane Fluidity

Bacteria can encounter a wide range of environments and must adapt to new conditions in order to survive. As the selective barrier between living cells and their environment, the plasma membrane plays a key role in cell viability. The barrier function of the cytoplasmic membrane is known to depend critically on the physical state of lipid bilayers, making it susceptible to changes in

environmental temperature. In fact, it has been established that normal cell function requires membrane lipid bilayers that are largely fluid; indeed, the bilayers of most organisms are entirely or mostly fluid at physiological temperatures. However, at lower temperatures, membrane lipid bilayers undergo a reversible change of state from a fluid (disordered) to a nonfluid (ordered) array of the fatty acyl chains. The temperature at the midpoint of this transition is called the transition temperature, and the change of state accompanying an increase in temperature is called the lipid phase transition, the gel–liquid crystalline transition, or most properly, the order–disorder transition. The transition temperature is a function of the membrane lipid composition and, in organisms deficient in cholesterol, mainly depends on the fatty acid composition of the membrane lipids. The (overly simplified) rule of thumb is that phospholipids that contain UFAs have much lower transition temperatures than those lipids made of saturated fatty acids. The effect is due to different packing of the two types of phospholipid acyl chains. Saturated fatty acid acyl chains can pack tightly, but the steric hindrance imparted by the rigid kink of the *cis* double bond results in much poorer chain packing of UFAs, even below the phase transition temperature. From these considerations, it seems clear that bacteria must regulate their phase transition in response to temperature. Without regulation, an organism shifted from a high to a low temperature would have membrane lipids with suboptimal fluidity, resulting in subnormal membrane function. The mechanism of regulation in all of the cases examined seems to occur via the incorporation of proportionally more UFAs (or fatty acids of analogous properties) as the temperature decreases. This regulatory mechanism, called thermal control of fatty acid synthesis, seems to be a universally conserved adaptation response allowing cells to maintain the appropriate fluidity of membrane lipids regardless of the ambient temperature. In this section, we discuss the basic features of thermal regulation of membrane lipid fluidity in *E. coli* and *B. subtilis*, in which the proposed mechanisms are firmly based on both genetic and biochemical evidences. There are two fundamental differences between the *E. coli* and *B. subtilis* models that account for the formation of UFAs and the regulation by growth temperature of the synthesis of these fatty acids. First, *B. subtilis* lacks the *fabB* and *fabA* genes that are essential for UFA synthesis in *E. coli*, and this property accounts for the absence of UFA production by the Gram-positive synthase. Instead, *B. subtilis* makes UFAs via an oxygen-dependent desaturase that uses existing phospholipids as substrates to introduce a double bond at the 5 position of the fatty acyl chain. Second, *B. subtilis* uses a two-component system composed of a membrane-associated kinase, DesK, and a transcriptional regulator, DesR, which stringently control the transcription of the gene coding for the desaturase. Induction of this pathway is brought about via the ability of the molecular thermosensor, DesK, that sense changes in the lipid bilayer structure triggered by a sudden decrease in temperature. In contrast, in *E. coli*, there is a biochemical mechanism that allows the elongation cycle of fatty acid synthesis to respond to the environmental temperature. In this organism, the UFA synthesized in greater quantity at low temperatures is C18:1 Δ^{11} . This regulatory response is due to the properties of FabF that converts C16:1 Δ^9 to C18:1 Δ^{11} . This enzyme is present at all temperatures but is more active at low temperature (Figure 2(a)). Thus, a cytosolic thermosensor governs the temperature-dependent adjustment on membrane fluidity in *E. coli*, and probably in related bacteria, while in *B. subtilis* this control is exerted by a membrane-associated thermosensor.

Fatty Acid β -Oxidation

Many bacteria are capable of degrading exogenous fatty acids as a carbon source for growth. *E. coli* can use fatty acids with various chain lengths as sole carbon and energy sources. After uptake, fatty acids can either be degraded via the β -oxidation pathway or used as precursors for membrane phospholipids biosynthesis. The degradation pathway is catalyzed by the enzymes encoded by the *fad* regulon, which are responsible for the transport and activation of long-chain fatty acids, and their β -oxidative cleavage into acetyl-CoAs. The biochemistry of the inducible enzymes of β -oxidation has been extensively studied and the pathway for degradation is defined. Transcriptional control of the fatty acid degradation genes occurs via the FadR regulatory protein, which is also an extensively studied fatty acid-responsive transcription factor (see 'Biosynthesis of UFAs'). When long-chain fatty acids of more than 14 carbons are present in the growth medium, they are internalized and converted to acyl-CoAs, which bind to FadR, causing release of the regulatory protein from the operator and thus derepression of transcription of the *fad* genes. Furthermore, FadR negatively regulates the expression of two gene products that are involved in anaerobic degradation of fatty acids. Thus, FadR in *E. coli* functions as a repressor of many genes mainly involved in growth on fatty acids.

B. subtilis cannot grow well on acetate as the sole carbon source, probably due to its lack of the glyoxylate shunt enzymes. Growing *B. subtilis* cannot degrade long-chain fatty acids added to the culture medium. These results suggest that fatty acid degradation through β -oxidation is insignificant. However, *B. subtilis* possesses a considerable number of genes involved in oxidation of fatty acids. This conservation suggests that the β -oxidation of fatty acids has some functions under certain physiological functions, such as differentiation, since a *fad* operon is induced at the onset of sporulation. Five *fad* operons are repressed by FadRBs. In a similar manner to *E. coli* FadR, the binding of FadRBs to its DNA targets is inhibited by long-chain acyl-CoAs.

Antibacterial Agents that Target Fatty Acid Biosynthesis

The fatty acid biosynthetic pathway is an attractive but still largely unexploited target for the development of new antibacterial agents. Several compounds empirically selected as inhibitors of bacterial growth owe their antibacterial to inhibition of fatty acid synthetic enzymes, being the most important example the antitubercular drug, isoniazid, which specifically inhibits the InhA enoyl-ACP reductase (FabI) from *Mycobacterium tuberculosis* (see 'The Type II Fatty Acid Biosynthetic Pathway'). The antiseptic agent

triclosan also targets FabI. However, a drawback to the development of FabI inhibitors as broad spectrum antimicrobial is the existence of a nonhomologous isozyme, FabK, in clinically important pathogens, such as *S. pneumoniae* (see 'The Type II Fatty Acid Biosynthetic Pathway'). It should be noted that there are many examples of natural products, such as thiolactomycin, cerulenin, and platensimycin that have evolved to target the FabF and FabB condensing enzymes. Although fatty acid synthesis inhibitors may not be effective against some Gram-positive bacteria that are supplemented with extracellular fatty acids; there is compelling evidence that such inhibitors are useful against many Gram-positive and all Gram-negative organisms even in the presence of extracellular fatty acids.

Engineering of Fatty Acid Biosynthesis for Biofuel Production

In the last years, bio-based sustainable production of fuels has been attracting increasing interest. Fatty acid derived compounds like alkanes, alkenes, ethylesters and fatty alcohols are of high energy content, and similar to the petro-based fuels currently in use. Production of these molecules has been achieved in genetically modified microorganisms, principally in *E. coli*, employing plant derived sugars and byproducts of agro-industrial processes. To this end, thioesterases, acyl-CoA ligases, several reductases and wax synthases have been expressed in different combinations in *E. coli*, as depicted in Figure 5. Improvements, like overexpression of

Figure 5 Biosynthesis of fatty acid-derived biofuels. Acyl-ACPs are reduced to fatty aldehydes by acyl-ACP reductases (AAR). Alternatively, the acyl-moiety can be released by the action of thioesterases (Tes). Free fatty acids are in turn activated to acyl-CoAs by acyl-CoA synthase (ACS). In biodiesel production the acyl-CoAs are esterified with ethanol by an acyltransferase (Atf), generating ethylesters of fatty acids. Acyl-CoAs can be also reduced to fatty aldehydes by Acyl-CoA reductases (ACR). Fatty aldehydes can be reduced again to fatty alcohols in a reaction catalyzed by ACR or fatty aldehyde reductase (FAR). Decarbonylation of fatty aldehydes by aldehyde decarbonylase (AID) produces alkanes (when the acyl group R is saturated) or alkenes (if R is unsaturated).

ACC and knock down of β -oxidation pathway, have increased production yields. The adequate election of the thioesterase employed permits to control the length of the fatty acyl chain. Although associated costs are still high and current efficiency does not allow massive production of these biofuels, several fermenting pilot plants have been constructed and started to work recently, showing promising results.

Lipopolysaccharide Structure

Lipopolysaccharide (LPS) is an essential component within the outer membranes (OM) of almost all Gram-negative bacteria. The LPS glycolipid is less abundant than glycerophospholipids but approximately 2×10^6 molecules cover ~75% of the cell surface of bacteria like *E. coli*. LPS is often called “endotoxin,” a term first introduced in the 19th century to describe the component of Gram-negative bacteria responsible for the pathophysiological phenomena associated with Gram-negative bloodstream infections. Early structural analyses of LPS were driven, in part, by the desire to resolve the identity of the molecule responsible for the endotoxic effect. The development of techniques for the extraction and isolation of LPS by O. Westphal, O. Lüderitz, C. Galanos and colleagues in the 1950s and 1960s represented a key breakthrough and most current methods are still based on the original hot phenol-water and aqueous phenol–chloroform–petroleum ether extraction procedures. This pioneering early work led to the understanding that LPS is responsible for the endotoxic activity, and, equally importantly, that different Gram-negative bacteria possess LPS molecules with similar overall compositions. Biophysical methods (nuclear magnetic resonance spectroscopy and mass spectrometry) now offer high resolution insight into the range of structural diversity.

The prototypical LPS of *E. coli*, *Salmonella enterica* and other members of the family *Enterobacteriaceae* is organized into three distinct structural domains: lipid A, core oligosaccharide (core OS) and O-antigen polysaccharide (OPS) (Fig. 1). This tripartite LPS structure is known as “smooth LPS” (S-LPS), taking its name after the “smooth” or shiny colony morphology displayed by enteric bacteria that have S-LPS on their cell surface. Mutants with defects in OPS or core OS assembly produce truncated LPS molecules but their growth in vitro is unaffected. For example, the widely used *E. coli* K-12 strains carry a defect in OPS biosynthesis. The resulting colonies lack the smooth character, and, therefore, the truncated LPS are widely known as “rough LPS” (R-LPS) (Fig. 1A and B). Preparations of LPS from bacteria that produce S-LPS contain a heterogeneous mixture of molecules with differing OPS chain length and always have a variable amount of truncated R-LPS. This molecular heterogeneity is clearly evident when LPS preparations are examined by SDS-PAGE (Fig. 1B). Some bacteria, particularly mucosal pathogens, naturally lack OPS chains in their LPS. Their LPS contains oligosaccharide extensions attached to various residues within a typical inner core OS, in a form known as lipooligosaccharide (LOS) (Fig. 1A). The role of lipid A in establishing the essential barrier function of the OM places constraints on the extent of its structural variation. In contrast, the outer part of the LPS molecule interacts with environmental factors, such as components of the host immune response and LPS-specific bacteriophages. These selective pressures may have played a significant role in the diversification of outer LPS structures.

While LPS has been considered as a biomarker for Gram-negative bacteria, some bacteria lack this molecule. In *Sphingomonas* sp. glycosphingolipids likely serve as functional replacements for lipid A. The situation in endosymbionts (e.g., *Wolbachia*, *Borrelia* species) is less clear. In LPS-producers, it is generally thought that lipid A is essential for viability. However, the universality of this assumption was challenged by the identification of a viable *Neisseria meningitidis* mutant containing a defect in an essential step in the lipid A biosynthesis pathway. The recent identification of “LPS-less” clinical isolates of *Acinetobacter baumannii* offers fascinating insight; these mutants have elevated contents of surface lipoproteins, suggesting an alternative strategy to form a viable OM.

Lipid A

Despite the challenges imposed by its heterogeneity and amphipathic properties, lipid A structures from many bacterial species have now been resolved, revealing a family of structurally related glycolipids based on common architectural principles. Free lipid A generally does not exist on the surfaces of bacteria, due to constraints within LPS assembly and export processes (see below). *Francisella tularensis* provides an exception, with only small quantities of the total cellular lipid A found in a complete LPS. The prototypical lipid A from *E. coli* possesses a carbohydrate backbone composed of two (β-1,6-linked) glucosamine (GlcN) residues,

[☆]Change History: November 2018. Chris Whitfield and Bradley R Clarke prepared the update. Modified sections “Lipopolysaccharide Structure, LipidA, Core Oligosaccharides, O Polysaccharides, Lipooligosaccharides, Biosynthesis and Assembly of Lipopolysaccharides, Biosynthesis of Lipid A-Core OS, Synthesis of O-Polysaccharides.” Added: “LPS Translocation-MsbA and the Lpt Machine, Functions and Biological Activities of Lipopolysaccharides changed to Protective Functions of LPSRole of LPS in Outer Membrane Integrity, O-Polysaccharides as a Protective Barrier” replaced with “Resistance to Polycations and Protective Roles of O-Polysaccharides” and “Molecular Mimicry, Lipopolysaccharide and Gram-negative sepsis replaced” with “Biological (Endotoxic) Activities of Lipopolysaccharides, Lipid A Modification Systems and Phase Variation and Molecular Mimicry in LPS, and LOS and Phase Variation and Molecular Mimicry in LPS and LOS” were incorporated into other sections. Removed “Biotechnological Applications Involving LPS”. Figures: figs 1 and 2 were combined and modified, fig 3 now fig 2 and legend modified, fig 4 now fig 3 and modified, fig 5 now fig 4 and modified, fig 6 now fig 5 and modified, fig 7 now fig 6 and modified, fig 8 now fig 7 and modified, fig 9 removed.

This article is an update of A.X. Tran, C. Whitfield, Lipopolysaccharides (Endotoxins), *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 513–528.

Fig. 1 (A) Schematic diagram showing different forms of LPS molecules. The tripartite S-LPS structure is typical of LPSs produced by members of the *Enterobacteriaceae*, *Pseudomonadaceae* and *Vibrionaceae*. These bacteria also produce a variable amount of R-LPS that lacks OPS and, in some cases, part of the core OS. Mucosal pathogens such as *Neisseria* and *Haemophilus* spp. lack OPS but instead may have phase-variable oligosaccharide extensions attached to the core OS, to form LOS. Only a few bacteria produce free lipid A. (B) Characteristic SDS-polyacrylamide gel profiles of R-LPS and S-LPS preparations.

which are phosphorylated at positions 1- and 4' (Fig. 2). However, in some cases (e.g., *Brucella abortus*, *Campylobacter jejuni*, *Leptospira interrogans*, *Rhizobium* and *Bradyrhizobium* species), a diamino-derivative (2,3-diamino-2,3-dideoxy-glucose; GlcN3N)) can replace one or both GlcN residues. The backbone is acylated with ester and amide-linked 3-hydroxyl saturated fatty acids (3-OH-C14:0). In *E. coli* and *Salmonella*, the fatty acyl chains on the nonreducing GlcN residue are substituted by nonhydroxylated fatty acids, creating an asymmetric arrangement in the classic hexaacyl structure. However, the precise acylation pattern is species specific (Fig. 2). In some nitrogen-fixing plant symbionts (e.g., *Rhizobium* and *Bradyrhizobium*), the fatty acids of the nonreducing GlcN3N residues are substituted with very long chain fatty acids (VLCFAs; 26–34 carbons). One or both VLCFAs are additionally substituted with hopanoid residues, complex pentacyclic triterpenoid lipids that also occur in the free form in the membranes of these organisms. VLCFAs can span the lipid bilayer and, together with the hopanoids, stabilize the outer membrane and protect against detrimental compounds within the root nodule. Mutants, defective in hopanoid synthesis are unable to persist as symbionts.

Within a given species structural variants arise due to modifications such as the addition of sugars including 4-aminoarabinose (Ara4N), galacturonic acid (GalA), GlcN, hexoses (mannose) and phosphoryl ethanolamine (PEtN) to the phosphate residues. Additional modifications include addition or removal of acyl chains. These modifications are constitutive in some bacteria but, in others, they are the result of complex environmental regulation. The additional glycoforms are not essential for viability in the laboratory but play important roles in host-bacterium interactions.

Core Oligosaccharides

For the purpose of discussion of structure-function relationships, the core OS is often conceptually divided into inner and outer core regions (Figs. 1 and 3). In all known LPS structures, α -linked 3-deoxy-D-manno-octulosonic acid (Kdo) or variants including, D-glycero-D-talo-octulosonic acid or 8-amino-3,8-dideoxy-Kdo, provide the linking sugar between the 6'-position of lipid A and the rest of the carbohydrate backbone. While Kdo is generally considered to be a diagnostic marker of LPS, this sugar is also now known to be present in some OPSs and (in its β -linked form) in a linker attaching a terminal lipid to some capsular polysaccharides in Gram-negative bacteria. Another common component of the inner core is L-glycero-D-manno-heptose (Hep). In the *Enterobacteriaceae*, the base inner core region is highly conserved and the phosphorylated glycan backbone is nonstoichiometrically modified by PEtN and additional Kdo and rhamnose residues (Fig. 3). In contrast, the outer core shows more diversity; for example, there are 5 outer core OS structures in *E. coli* reflecting variations in glucose components and linkages. In most cases, the core OS carries a net negative charge that is important for its function in establishing a stable OM permeability barrier (see section "Protective Functions of LPS"). The charge is contributed by the carboxyl groups of Kdo and phosphate in *E. coli* and *Salmonella* but galacturonic acid residues (GalA) achieve this role in *K. pneumoniae*.

Fig. 2 Structural diversity of representative lipid A molecules found in pathogenic bacteria. The major lipid A species from *Helicobacter pylori* and *Neisseria meningitidis* are compared to the unmodified “basic” lipid A of *Escherichia coli* K-12. Regulated covalent modifications (red) are indicated with dashed bonds. The lengths of the fatty acyl chains are indicated with the numerals enclosed by circles.

of sialic acid, and this is important for entry of the bacterium into human mucosal epithelial cells. In contrast, variants with highly sialylated LPS resist killing by complement and antibodies but fail to enter the epithelial cells. The complex glycoforms preclude precise determination of LOS structures unless phase-locked variants are available. Some bacteria (e.g., *Bordetella* spp.) can form both S-LPS and LOS.

Biosynthesis and Assembly of Lipopolysaccharides

As might be anticipated from the structure of LPS, the processes involved in LPS biosynthesis are complex (Fig. 4A). A further complication arises from the fact that most LPS precursors are found in the cytoplasm and the completed molecule must be assembled in a process that traverses the inner membrane, the periplasm, the peptidoglycan layer and the outer membrane. In overview, lipid A-core is synthesized in consecutive steps and is then exported across the inner membrane by MsbA, an ATP-binding cassette (ABC) transporter. OPS is assembled on the lipid acceptor, undecaprenol-phosphate (und-P; the same carrier used in peptidoglycan and teichoic acid biosynthesis), and becomes available at the periplasmic face of the inner membrane in the und-PP-linked form. The LPS molecule is completed by transfer of the OPS to the lipid A-core before its translocation to the cell surface by the multiprotein Lpt machine. These processes establish a basal LPS structure but a variety of postsynthetic reactions can remodel these products in order to fit a particular lifestyle or respond to changing environmental cues. These remodeling reactions are described later in the context of their impact on LPS properties and functions (see sections “Protective Functions of LPS” and “Biological (Endotoxic) Activities of LPS”).

Fig. 4 (A) Overview of LPS biosynthesis. The lipid A-core domain is synthesized at the cytoplasmic face of the inner membrane and is exported to the periplasm by MsbA, an ABC transporter protein. The O-polysaccharide (O-antigen) is assembled separately on a lipid carrier (undecaprenol-phosphate) and is ligated to lipid A-core by WaaL in the periplasm. Both completed S-LPS molecules and R-LPS molecules are transported to the cell surface by the envelope-spanning Lpt protein complex. (B) The transenvelope Lpt complex. Lpt proteins extract nascent LPS molecules from the cytoplasmic membrane and translocate them via a periplasmic scaffold to the outer membrane. The translocation process is driven by ATP hydrolysis.

Biosynthesis of Lipid A-Core OS

The pathway for the biosynthesis of lipid A was established through systematic efforts in the laboratory of Chris Raetz; the pathway is widely referred to as the “Raetz pathway” (Fig. 5). The nine Lpx enzymes of the constitutive Raetz pathway are highly conserved and a single copy of each *lpx* gene can be found in the genome of most Gram-negative bacteria and, interestingly, in some plants. The biochemistry of each step is resolved and structures are available for the key enzymes. The pathway begins in the cytoplasm of the cell with the reversible acylation of the sugar nucleotide UDP-*N*-acetylglucosamine (UDP-GlcNAc), catalyzed by LpxA. UDP-GlcNAc is also a precursor for peptidoglycan biosynthesis. The second (and first committed) step of the pathway, catalyzed by LpxC, is well-regulated. LpxC is a metalloamidase with a unique structure, making it an attractive target for drug discovery. Hydroxamate compounds (e.g., CHIR-090; *N*-aroyl-L-threonine hydroxamic acid) are potent inhibitors. LpxC-catalyzed deacetylation allows the addition of a second fatty acyl chain catalyzed by LpxD, forming UDP-2,3-diacylglucosamine. LpxH then cleaves the pyrophosphate bond of the UDP-2,3-diacylglucosamine intermediate to yield UMP and lipid X. Elucidation of the reaction sequence was made possible by the initial discovery of this intermediate, more than 20 years ago. The disaccharide synthase, LpxB, forms the characteristic β -(1,6) glycosidic linkage in the disaccharide backbone and is followed by phosphorylation at the 4'-position by a specific kinase, LpxK, to generate lipid IV_A, a key lipid A precursor. A distinctive feature of the Gram-negative bacterial LPS is the presence of Kdo at the 6'-position of the disaccharide backbone. In *E. coli* and *Salmonella*, transfer of the Kdo sugars is catalyzed by the bifunctional Kdo transferase, WaaA. The Kdo transferase from other organisms can be monofunctional (e.g., *Haemophilus* and *Vibrio* species) or trifunctional (e.g., *Chlamydia* species). In *E. coli* and *Salmonella*, the synthesis of Kdo₂-lipid A (Fig. 5) is completed by the addition of two fatty acyl chains by the so-called “late” or secondary acyltransferases, LpxL (lauroyl, C12) and LpxM (myristoyl, C14).

The completed Kdo₂-lipid A provides an acceptor for glycosyltransferases that act sequentially to assemble the core OS, as well as those that add the oligosaccharide chains of LOSs. Assignments of glycosyltransferases that synthesize core OS and enzymes such as kinases that modify the backbone have primarily been made by approaches where specific genes are individually mutated and the resulting LPS structure is resolved by chemical and physical analysis. In some cases, these mutations have complex effects since they alter the structure of the acceptors for additional enzymes, that is, a single mutation can give a phenotype suggesting multiple defects. For some enzymes detailed biochemical properties and solved structures are now available.

Fig. 5 The pathway for biosynthesis of the Kdo₂-lipid A domain of LPS in *Escherichia coli* K-12. The enzymes (red) responsible for each step in the pathway are indicated. All have been identified by genetic and biochemical approaches. The completed Kdo₂-lipid A can serve as an acceptor for sequential assembly of the core oligosaccharide at the inner face of the cytoplasmic membrane. Acyl-acyl carrier proteins (ACP) are the obligate donors for acylation in the pathway. The ABC transporter MsbA is responsible for exporting the complete Kdo₂-lipid A (or core-lipid A) molecule across the cytoplasmic membrane.

Synthesis of O-Polysaccharides

Despite the diversity in OPS structures, only three mechanisms are known for their assembly. OPS synthesis begins at the cytoplasmic face of the inner membrane with activated precursors (sugar nucleotides; NDP-sugars) and the process terminates with a nascent OPS at the periplasmic face (Fig. 4A). Undecaprenol phosphate (und-P) is an obligatory carrier in all three OPS assembly pathways. As a result, all are initiated by phosphoglycosyltransferases (PGTs) that transfer a sugar-1-phosphate from UDP-hexose or UDP-acetamidohexose donors to Und-P. The ligase (WaaL) from *E. coli* K-12 will ligate structurally distinct OPSs formed by any pathway, indicating that the form in which nascent OPS is presented for ligation is conserved. The three pathways for assembly of O antigens vary in the components required for polymerization, in the cellular location of the polymerization reaction, and in the manner in which material is exported across the inner membrane (Fig. 6). Similar mechanisms are identified in the biosynthesis of capsular polysaccharides in Gram-negative and Gram-positive bacteria.

The earliest known pathway for OPS synthesis is distinguished by the involvement of the putative “OPS polymerase” enzyme, Wzy. The “Wzx-Wzy-dependent” system (Fig. 6) is the classical pathway first described in *S. enterica* in the 1960s by H. Nikaido, M.J. Osborn, P. Robbins, A. Wright and others. The OPSs synthesized by this pathway are all heteropolymers and often have branched repeating unit structures. Und-PP-linked O-repeat units are assembled by glycosyltransferase enzymes at the cytoplasmic face of the inner membrane by the sequential action of an integral membrane PGT and additional peripheral glycosyltransferases. The Wzy polymerization reaction occurs at the periplasmic face of the membrane and utilizes und-PP-linked OPS-repeat units as the substrate. These are supplied by an integral membrane protein transporter, Wzx, a member of the Multidrug/Oligosaccharidyl-lipid/Polysaccharide (MOP) family. Polymerization of the OPS repeat units minimally involves the putative polymerase (Wzy) and the OPS chain length regulator (Wzz) and genetic data suggest critical interactions between Wzx, Wzy and Wzz. Polymerization occurs in a block-wise process where the growing glycan is transferred from its lipid carrier to the newly exported und-PP-linked repeat unit. A *wzy* mutant is unable to polymerize OPS and its LPS comprises a single O-repeat unit attached to lipid A-core (sometimes called “semirough” SR-LPS). In contrast, a *wzz* mutant makes S-LPS but loses the characteristic modal distribution (Fig. 1B) of OPS-chain lengths evident in SDS-PAGE analysis. The presence of additional Wzz proteins in some bacteria can generate LPS species with multiple discrete clusters of O-PS sizes.

In the “ABC-transporter-dependent” pathway (Fig. 6) the OPS is synthesized exclusively inside the cytoplasm and once complete, it is exported to the periplasm via an ATP-binding-cassette (ABC) transporter. OPSs from this pathway typically lack glucose side branches, although these can be added later (see section “Protective Roles of O Polysaccharides”). As in the Wzy-dependent pathway, synthesis is initiated at the cytoplasmic face of the inner membrane by a PGT enzyme and peripheral glycosyltransferases then act sequentially to elongate the und-PP-linked intermediate at the nonreducing terminus to form a fully polymerized und-PP-OPS. In some examples, polymerization is terminated by the addition of a residue that caps the chain. In such cases, the assembly system employs an extended coiled-coil structure that separates the capping enzyme from the polymerizing enzymes. This serves as a molecular ruler to establish OPS chain length. The cognate ABC transporter possesses a carbohydrate-binding module that selects only capped chains for export. In systems lacking the capping strategy, chain-length determination is less precise and is dictated by protein: protein interactions involving the biosynthesis machinery and the ABC transporter. The mechanism by which an ABC transporter can translocate a long chain OPS linked to und-PP across the cytoplasmic membrane is intriguing. The recent structure of a putative O-antigen ABC transporter suggests a processive model in which multiple rounds of

Fig. 6 The three known pathways for the biosynthesis of O-polysaccharide (OPS). Each of the assembly systems initiate at the cytoplasmic face of the inner membrane with an undecaprenyl pyrophosphoryl (und-PP)-linked intermediate. The initiating reaction proceeds by addition of a sugar-1-phosphate from a nucleoside diphosphosugar (NDP-sugar) and is catalyzed by a phosphoglycosyltransferase (PGT). Subsequent additions by glycosyltransferases (GT) involve only the sugar residues from NDP-sugars. The enzyme complexes include both integral and peripheral membrane proteins and key components are indicated by name. The pathways differ in the mechanism and location of O-PS polymerization and in the manner by which OPS (or O-repeat units) are transferred across the cytoplasmic membrane. Termination of OPS synthesis occurs with ligation of the nascent OPS to preformed lipid A-core OS at the periplasmic face of the membrane.

ATP binding and hydrolysis are required to complete the task. A model based on PglK, a bacterial ABC transporter of Und-PP-oligosaccharides for protein N-glycosylation proposed only the glycan enters the central cavity of the transporter complex and the same is likely true for OPS.

The “synthase-dependent” pathway for OPS biosynthesis is, so far, confined to the one homopolymeric O antigen (factor 54) of *S. enterica* serovar Borreze. The model for this pathway (Fig. 6) proposes that the initiating PGT forms an und-PP-sugar acceptor that is elongated and exported by a single multifunctional synthase enzyme, in a manner analogous to cellulose synthases and hyaluronan synthases.

LPS Translocation—MsbA and the Lpt Machine

Export of lipid A–core across the membrane to the periplasm is achieved by the conserved ABC transporter, MsbA. MsbA is essential for viability in *E. coli* and depletion of its activity in temperature-sensitive mutants results in the accumulation of Kdo₂-lipid A and glycerophospholipids in the inner membrane. Crystal structures of MsbA transporters from several species are available but a key question remains—how does MsbA handle an amphipathic export substrate; that is, what is the transport solution for a molecule with a highly hydrophobic acylated domain and a polar carbohydrate backbone? MsbA is highly selective for the hexaacylated LPS forms, but full acylation only occurs after the addition of 2 Kdo residues to a tetraacyl lipid A in *E. coli*. Thus, defects in Kdo addition are manifested as blocks in LPS export and the growth defects can be overcome by compensatory mutations in MsbA. MsbA specificity therefore defines the minimal LPS structure required for growth of *E. coli* and *Salmonella*; Kdo₂-lipid A (sometimes referred to as chemotype *Re*-LPS). In other bacteria where the order of Kdo addition and secondary acylation is not conserved, the minimal structure may differ.

Translocation of LPS to the cell surface is completed by the LPS transport machine, composed in *E. coli* of seven conserved proteins that form subcomplexes in the inner and outer membranes with a connecting bridge (Fig. 4B). The functional complex and stable bridge have been reconstituted in proteoliposomes, resolving any lingering debate about whether transport across the periplasm involved a contiguous structure or soluble chaperones. LptBFG form an ABC-transporter complex that appears to extract LPS molecules from the cytoplasmic membrane. The LPS is then passed to the outer membrane via a bridge composed of the periplasmic domain of LptC, several copies of LptA, and an N-terminal domain of LptD. These proteins/domains share a common β -jellyroll fold, where the acyl chains of the LPS molecule are sequestered from the aqueous periplasm between the two β -sheets of each component. At the OM, the LPS enters the LPS translocon (LptDE) which possesses a lateral gate to allow the release of the LPS into the outer leaflet of the OM. The unidirectional translocation system is driven by ATP turnover by the ABC protein complex with successive LPS molecules pushing their predecessors through the conduit in a model analogous to a PEZ candy dispenser.

Protective Functions of LPS

LPS is a crucial component of the OM and is well known for its major role in establishing a permeability barrier. However, each part of the LPS molecule performs protective functions against different environmental factors.

Role of LPS in the Outer Membrane Integrity

OM asymmetry (i.e., LPS in the outer leaflet and glycerophospholipids in the inner leaflet) is essential to the barrier properties. When this is not achieved, and glycerophospholipids migrate to the outer leaflet, the resulting areas of the outer membrane become permeable to large hydrophobic antibiotics, detergents such as SDS and bile salts (sodium cholate and deoxycholate) that normally only affect Gram-positive bacteria. Secondary acyl chains are implicated in maintaining a low degree of fluidity, a condition that is critical to outer membrane function. Although secondary acyl chains are not essential for viability, under-acylation of lipid A often results in growth defects. The normal tight packing of saturated acyl chains induces a network of hydrophobic interactions that help maintain the integrity of the outer leaflet of the outer membrane through van der Waals' forces. Stability also involves lateral interactions between adjacent LPS molecules and between LPS and OM proteins. These interactions are dependent on negatively charged elements, including the terminal phosphates of lipid A, core OS phosphates and carboxyl groups from residues such as Kdo or galacturonic acid. These may participate in divalent cation bridges that minimize electrostatic repulsion while promoting strong lateral interactions. An illustration of the importance of these lateral interactions is provided by “deep-rough” mutants of *E. coli* and *Salmonella*, which show hypersensitivity to hydrophobic compounds and other physiological changes. The phenotype is conferred by loss of core OS heptose and loss of phosphorylation catalyzed by the WaaP kinase. In *Pseudomonas aeruginosa*, addition of core OS phosphates is essential for viability and nonphosphorylated molecules are not efficient substrates for the Lpt system. Core OS phosphorylation may provide further avenues for therapeutic intervention.

Resistance to Polycations

Polycations including host-produced cationic antimicrobial polypeptides (CAMPs) and antibiotics such as polymyxin B and colistin exploit negative charges in the LPS structure to breach the outer membrane. As a result, bacteria exploit a variety of postsynthetic strategies to reduce the charge content and several examples are now well documented. Many changes simultaneously

result in alterations in endotoxic activity (see section “Biological (Endotoxic) Activities of Lipopolysaccharides”). Some modifications are constitutive. At a simplest level, some bacteria reduce the complexity of their LPS species. While the Raetz pathway and the specificity of MsbA imposes a minimal structural requirement for export (Kdo₂-lipid A), *Helicobacter pylori* removes two acyl chains and the phosphate groups to protect against CAMPs. In *F. tularensis*, Kdo is removed to yield free lipid A. A different constitutive modification occurs in *Vibrio cholerae* O1, where the classical and El Tor biotypes are distinguished by the resistance of El Tor to polymyxin B. This is mediated by glycine (or diglycine) moieties added to the acyl chain at the 3' position of lipid A by a process resembling nonribosomal peptide synthetases.

In other bacteria, exposure to polycations results in a highly-regulated LPS remodeling response. *S. enterica* provides a classic example and has contributed to much of our understanding of lipid A remodeling processes in general. The PhoP/Q and PmrA/B two-component phosphorelay regulatory systems respond to environmental cues (e.g., low Mg²⁺ and CAMPs, or mildly acidic pH, Fe³⁺, respectively) and transcriptionally regulate a variety of remodeling genes. Many changes involve the acylation pattern. For example, PhoP/Q signaling upregulates PagP, an outer membrane protein that transfers a palmitoyl group from glycerophospholipid to the acyl chain at position 2 on lipid A. PagP is important for CAMP resistance and PagP homologues are essential for virulence of a variety of bacteria. In addition, PhoP/Q-regulated deacylases (PagL and LpxR) remove ester-linked fatty acids. In *Klebsiella pneumoniae*, a common pathogen of immunocompromised individuals, LPS is modified in a tissue-specific manner. In the lungs only, LpxO adds a 2-hydroxyacyl moiety on the lipid A to confer CAMP resistance and this is accompanied by resistance to colistin, a drug of last resort for treating multidrug resistant *K. pneumoniae*. Addition of colistin to growth media triggers this lipid A modification outside the host. One of the best characterized modifications in *S. enterica* is the addition of Ara4N to the lipid A phosphates. As this modification occurs in the periplasm, the direct glycosylation donor is not a nucleotide diphosphosugar. Instead, a three-enzyme system synthesizes Und-P-Ara4N, exports it to the periplasm, and then transfers the Ara4N to lipid A. Interestingly, the same modification is constitutive in *Burkholderia cepacia*, where the specificity of the LptBFG complex ensures that only appropriately modified LPS species are translocated to the surface. In *Francisella* and *Bordetella* species, a comparable modification process adds galactosamine and GlcN, respectively. These examples illustrate the varied applications of related processes in different pathogens. Another common LPS modification is the addition of PEtN to lipid A and Kdo residues, or (in *Campylobacter jejuni*) to Hep. The enzymes in *S. enterica* are differentially regulated. This addition is particularly important for CAMP resistance in *N. meningitidis*, which cannot add Ara4N. Plasmid-encoded resistance to the last resort drug, colistin, is major healthcare threat. The MCR-1 enzyme responsible for resistance is a PEtN transferase that modifies lipid A.

Protective Roles of O-Polysaccharides

Molecular modeling of LPS structure and its organization in the outer membrane suggests that the OPS lies partially flat on the cell surface, where the crossover of multiple chains forms a “felt-like” network. Since OPS chains are flexible, they can also extend a significant distance from the surface of the outer membrane and cryo-electron microscopy reveals a significant OPS layer on the cell surface. It is therefore not surprising that many properties attributed to the OPS are protective. These are particularly important for pathogens to withstand the effects of host innate immune components including complement and bactericidal/permeability-inducing protein (BPI), an antibacterial product found in polymorphonuclear leukocyte-rich inflammatory exudates. BPI has multiple roles including lysis of bacterial cells, neutralizing LPS for clearance, and opsonization of bacteria for phagocytosis by neutrophils. OPS chain length plays a key role in resistance to both complement and BPI. Serum proteins in the complement pathway interact to form a membrane attack complex (MAC) that can integrate into lipid bilayers, leading to cell death. MACs can be formed via a “classical” pathway, initiated by surface antigen-antibody complexes, or by the “alternative” pathway, where the complement component C3b interacts directly with the cell surface in the absence of antibody. S-LPS does not prevent C3b deposition but the longest OPS chains preferentially bind C3b, so the resulting MAC is unable to insert into the OM. In addition to OPS chain length, complement-resistance is influenced by the extent of coverage of the available lipid A core with OPS. As is often the case, there are exceptions to such generalizations. For example, there are some *E. coli* strains with S-LPS that are serum-sensitive unless an additional capsular polysaccharide layer is present. Although R-LPS variants of *E. coli* and *Salmonella* are almost invariably serum-sensitive, other bacteria (including many with LOS) use alternate strategies to achieve resistance.

OPS can also mask surface molecules used as receptors by bacteriophages. However, OPS themselves provide receptors for some phages and this may be one of the biggest drivers of OPS diversity. In some bacteria, OPS structure is modified by activities encoded by lysogenic phages, presumably to prevent superinfection. A range of modifications have been recognized including acetylation, addition of PEtN and glycosylation. The glycosylation processes are well documented in members of the genera *Escherichia*, *Klebsiella*, *Salmonella* and *Shigella*. In these bacteria, three-enzyme modification systems use Und-P-Glc or Und-P-Gal to modify OPS in the periplasm in processes analogous to Ara4N modification of lipid A. The acceptors for modification are Und-PP-OPS molecules produced in Wzy- or ABC-transporter dependent pathways.

Molecular Mimicry

Molecular mimicry, a process where LPS substructures are identical or very similar to host glycans, is frequent in LPS and LOS. For example, the O-chain of *H. pylori* LPS contains fucosylated OS and Lewis antigen epitopes, which mimic human blood group antigens. Variable expression of these epitopes facilitates evasion of the host immune response and influences autoimmune responses, cell adhesion, and long-term colonization of the bacteria. The LOS of *C. jejuni* and *Brucella melitensis* contain

phase-variable ganglioside mimics and these may again provide a mechanism for avoiding the host immune response. However, they are also implicated in the development of an autoimmune response that underlies Guillain-Barré syndrome.

Biological (Endotoxic) Activities of Lipopolysaccharides

Mammals have evolved innate mechanisms for detecting and clearing microorganisms. These processes detect conserved microorganism-associated molecular patterns (MAMP) and elicit an immune response and bacterial killing through the production of inflammatory mediators such as tumor necrosis factor (TNF- α), interferons, and interleukins. However, continued stimulation of this response by invading pathogens can lead to life-threatening sepsis which is often manifested by fever and hypotension and can lead to disseminated intravascular coagulation and organ failure. In the United States, Gram-negative sepsis accounts for nearly 200,000 deaths each year. LPS (endotoxin) is the predominant MAMP exhibited by Gram-negative bacteria. Since free LPS is required to initiate the inflammatory process, treatment with antibiotics and the ensuing bacterial lysis can exacerbate the problem.

The key elements of the complex system by which mammalian cells respond to LPS have been identified (Fig. 7). Circulating LPS interacts with a variety of LPS-binding proteins including BPI and LPS-binding protein (LBP). LBP is an acute phase protein which delivers LPS to cell surface receptors to initiate signaling for production of inflammatory mediators. The signaling is initiated by LPS binding to CD14; CD14-knockout mice are 10,000-fold less sensitive to LPS in vivo. CD14 occurs as a glycosylphosphatidylinositol (GPI)-anchored glycoprotein attached to the membrane (mCD14) but nonmyeloid (endothelial and epithelial) cells respond to LPS via a soluble form of CD14 (sCD14). CD14 has a hydrophobic pocket that accommodates the acyl chains of lipid A. The slow and rate-limiting binding kinetics is overcome by LBP delivering LPS to CD14. LPS is then transferred to a cell-surface signaling complex of Toll-like receptor 4 (TLR-4) and myeloid differentiation factor 2 (MD-2). These proteins are both essential for LPS responsiveness. A crystal structure of TLR-4/MD-2 complexed with *E. coli* LPS has been solved. TLR-4 and MD-2 form a heterodimer and LPS binding induces an additional interaction between two TLR-4/MD-2 complexes.

TLR-4/MD-2 can promote two different signaling responses to LPS depending on lipid A structure and the source of the cells; mouse and human cells may respond differently to a given LPS. An immediate and strong inflammation response occurs through the myeloid differentiation primary response protein 88 (MyD88) pathway, leading to production of pro-inflammatory cytokines such as TNF, IL-6, and IL-12. The second response occurs after endocytosis of the TLR-4/MD-2 complex and involves the TRAM (TRIF-related adaptor molecule) and TRIF (TIR domain-containing adaptor inducing IFN) proteins in a pathway resulting in production of type I interferon which induces genes involved in a milder inflammatory response. Phosphorylated hexa-acylated lipid A signals both TLR-4-dependent responses. However, the LPSs of numerous pathogens such as, *Helicobacter pylori*, *Yersinia pestis*, *Francisella tularensis*, *Legionella pneumophila*, *Porphyromonas gingivalis*, and *Chlamydia trachomatis* all have lower biological activities. The ability of these pathogens to cause severe disease in humans may be due, in part, to their ability to preferentially promote TRAM/TRIF-dependent inflammation or to circumvent TLR-4 signaling altogether. These alternative biological effects may be a result of variations in binding properties of lipid A to the TLR-4/MD-2 complex and the ability to promote dimerization of the signaling complex.

The structure of lipid A generally dictates the biological (endotoxic) properties of LPS. Importantly, partial structures (including lipid IV_A) and some naturally occurring LPS are biologically inactive and can act as antagonists, abrogating the biological effects of "toxic" LPS. Understanding the structure-activity relationships, and the underlying biosynthetic foundation, affords the possibility of generating LPS species with predicted effects for vaccine adjuvants and therapeutics. The key structural principles underlying biological activity have been resolved. In the toxic hexaacyl lipid A of *E. coli*, the phosphates and the position and lengths of acyl chains are critical. MD-2 accommodates five of the acyl chains of lipid A with the sixth chain interacting with TLR-4. This is important for receptor dimerization. In contrast, lipid A molecules that show low biological activity typically possess only four or five acyl chains, some which are 16–18 carbons in length, and they contain only one phosphate group attached to lipid A. However, the presence of fewer acyl chains is not an absolute signal of reduced biological activity. In *B. caenocepacia* the Ara4N modification on lipid A allows exposure of the fifth acyl chain to promote receptor dimerization and a similar principle may underpin the enhanced activity of GlcN-modified lipid A from *B. pertussis*. While the lipid A moiety alone is usually responsible for TLR-4/MD-2 binding and activation, other regions of the LPS molecule are important for inducing inflammation in some bacteria. *Capnocytophaga canimorsus* is an oral commensal in dogs but can cause severe sepsis in humans. Its lipid A-core molecule is 20,000-fold more toxic than free (pentaacyl) lipid A and the carboxylate group of the core OS Kdo residue is critical for MD-2 interaction. Lipid A of *Brucella melitensis* is a poor agonist of the TLR-4/MD-2 pathway. The core OS contains a GlcN-rich side branch that is proposed to shield the lipid A portion and prevent efficient binding to the host cells. LPS lacking the side branch showed enhanced pro-inflammatory responses and reduced the ability of the bacteria to survive in bone marrow dendritic cells. Certain OPS structures (e.g., polymannose OPS of some isolates of *Hafnia alvei* and *E. coli*) also influence cytokine production. In this case, the OPS binds to Dectin-2 on the surface of myeloid cells and enhances the TLR-4/MD-2 response to lipid A. This synergy was only observed using complex S-LPS and was attributed to juxtaposition of Dectin-2 and TLR-4 following LPS binding.

Most studies have focused on the effect of LPS from a single organism. However, recent studies have reinforced the need to consider collateral effects in the microbiome. LPS from gut bacteria is generally considered to produce a strong TLR4-dependent response but recent work has shown that total LPS from gut populations is immunosuppressive. The underacylated lipid A structure in the *Bacteroidales* is believed to be responsible for immune silencing in the gut microbiome, to facilitate tolerance

Fig. 7 The pathways involved in stimulation of myeloid and epithelial cells by LPS. LPS-binding protein sequesters LPS from bacterial membranes or micelles and delivers it to CD14. Subsequently, LPS is transferred to the TLR-4/MD-2 complex and induces TLR-4/MD-2 dimerization. The cytosolic domains of TLR-4 can promote a strong and immediate inflammatory response through recruitment of TIRAP/MyD88 and/or a mild response after endocytosis of the TLR-4 complex and recruitment of the TRAM/TRIF proteins. Alternatively, bacterial OMVs or invasive Gram-negative bacteria can induce inflammation by activation of the caspase-11-dependent inflammasome pathway following escape of LPS from the early endosome.

of the gut microflora. Alterations of this critical hoemostasis to favor an inflammatory response can have wide-reaching effects in human health.

While the receptor-mediated signaling of external LPS has been intensively investigated, an additional noncanonical caspase-dependent inflammasome pathway detects LPS in the cytosol of mammalian cells. Intracellular pathogens such as *Salmonella*, *Burkholderia* and *Shigella* species can introduce LPS either directly into the cytosol, or by release from the endosome. However, most pathogens do not invade host cells and these organisms release LPS-containing outer membrane vesicles during growth. These are

taken up by host cells through clathrin-mediated endocytosis and released to the cytosol from the early endosome. This signaling pathway activates the caspase-1 protease, which cleaves and activates inflammatory cytokines IL-1 β and IL-18. Inflammasome activation can also lead to pyroptosis, a programmed cell death presumably aimed at eliminating invading bacteria. Oligomerization of caspase is central to the process and nontoxic LPS forms can bind to caspase without promoting oligomerization, consistent with their antagonistic effects in LPS-induced toxic shock.

The coverage here has focused on the LPS molecule as a signaling molecule for the innate immune system. However, a fascinating recent development has revealed the importance of heptose-1,7-bisphosphate, an intermediate in biosynthesis of a critical LPS precursor (ADP-heptose), also acts as a PAMP. Active release of heptose-1,7-bisphosphate has been documented in *Neisseria* and enters host cells by endocytosis, where it is recognized by a cytosolic pathway via the host tumor necrosis factor receptor-associated factor (TRAF)-interacting protein with forkhead-associated domain (TIFA) protein. In *Helicobacter pylori*, the same metabolite is translocated by the Cag type 4 secretion system and the resulting inflammatory response may have implications for stomach cancer.

Defining Statement

L. monocytogenes is a facultative intracellular Gram-positive bacterium able to invade, survive and replicate in phagocytic cells and non-phagocytic cells. *L. monocytogenes* has become a model to study the intracellular lifestyle of bacteria, and a powerful tool to study basic cellular biology processes.

Listeriology: An Historical Perspective

Historically, the first officially deposited strain of the human pathogen *L. monocytogenes* was isolated in 1924, by E.G.D. Murray, from rabbits and guinea pigs in animals exhibiting severe mononucleosis. Listeriosis was long considered as a zoonosis contracted through bacterial oral contamination. During the 1970s and 1980s, a number of outbreaks occurred in industrialized countries and led to the conclusion, in 1983, that *Listeria monocytogenes* was indeed the causal agent of food-borne listeriosis.

Several seminal discoveries or new approaches have changed our view on *Listeria*, and have contributed to make this organism one of the most studied bacterial pathogens. Following studies performed in the 1960s, *L. monocytogenes* became one of the primary pathogens used to study the T-cell immune response, due to its propensity to induce a rapid and protective cellular immune response after infection. Furthermore, the humoral immune response does not play a critical role in recovery from primary infection or protection against a secondary infection. The ability of *L. monocytogenes* to invade cells was first highlighted in 1970s. The molecular details underlying this ability have since been studied in great detail. In the mid 1980s, the use of molecular biology tools combined with cell biology approaches permitted the study of virulence factors, and the effect of *Listeria* on infected cells allowed researchers to unravel key concepts in cell biology. In 2001 the sequencing of the genomes of *L. monocytogenes* and *L. innocua* launched the still flourishing era of post genomics including comparative studies between *Listeria* species and between *L. monocytogenes* strains. More recently, the advent of and ever increasing accessibility of next generation sequencing and RNA-seq technology has contributed to more precise genome annotation and analysis of the bacterial transcriptional landscape in a variety of conditions both *in vitro* and *in vivo*.

Taxonomy

Listeria monocytogenes was first named *Bacterium monocytogenes* by E.G.D. Murray in 1926. It then received the name *Listerella hepatolytica* (Pirie, 1927). In 1940 Pirie suggested the name *Listeria monocytogenes* which became the name in the Approved Lists of Bacterial Names.

The genus *Listeria* belongs to the Firmicutes phylum and group with a low G+C content (38%). This sub-group includes *Clostridium*, *Bacillus*, *Enterococcus*, *Streptococcus* and *Staphylococcus* species. Furthermore, comparative analysis of *L. monocytogenes* EGDe and *L. innocua* CLIP 11 262 genomes revealed a conserved, co-linear organization of these two genomes and an unexpected synteny with the genomes of *B. subtilis* and *S. aureus*.

On the basis of DNA-DNA hybridization, multi-locus enzyme electrophoresis, rRNA gene restriction patterns and 16s rRNA sequencing, the genus *Listeria* includes ten currently recognized species and two subspecies: *Listeria monocytogenes*, *Listeria innocua*, *Listeria ivanovii* subsp. *ivanovii*, *Listeria ivanovii* subsp. *londoniensis*, *Listeria seeligeri*, *Listeria welshimeri*, *Listeria grayi*, *L. marthii*, *L. rocourtae*, *L. weihenstephanensis* and *L. fleischmannii*. Only *L. monocytogenes* and *L. ivanovii* are pathogenic, but *L. ivanovii* is strictly described as an animal pathogen, that is particularly associated with abortion in ruminants.

Bacteriological Characterization

General Characters of the *Listeria* Genus

Listeria spp. are small Gram-positive, non-spore forming, non-capsulated bacilli, facultative intracellular, aero-anaerobic bacteria. They possess 1 to 5 flagella that confer motility at low temperature (20°C). Many *Listeria* strains are nonmotile at 37°C due to a lack

★Change History: July 2014. L. Radosheвич and P. Cossart updated Abstract and the entire text. Figures were unchanged and added new references in 'Further reading'.

This article is an update of L. Dortet, E. Veiga-Chacon, P. Cossart, *Listeria monocytogenes*, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 182–198.

of flagellin expression at this temperature. The genome G + C percentage is between 36% and 42%. The *Listeria* peptidoglycan is of the type A1 γ (presence of meso-diaminopimelic acid in position 3 of the tetrapeptidic unit), which is the same as in most Gram-negative bacteria. It also contains teichoic and lipoteichoic acids. (Figure 1)

Growth Conditions: Temperature, pH, Salts

Listeria spp. are free-living, ubiquitous, environmental bacteria commonly found in soil, water, plants and decaying vegetation. However, the natural habitat or the preferred niche (e.g. amoeba) of *Listeria* has not been identified yet. *Listeria* spp. have also been isolated as commensal bacteria from the intestinal flora of bovines, birds and humans.

Listeria spp. are non-fastidious bacteria, able to grow in classical broth media such as Brain Heart Infusion (BHI), blood added gelosis or Luria broth (LB). In these media, *Listeria* growth is stimulated by addition of glucose (0.2 to 1). On solid media containing 5% of sheep, horse, rabbit or human blood, beta-hemolysis is observed around colonies of *L. monocytogenes*, *L. ivanovii* and *L. seeligeri*.

One of the hallmarks of *L. monocytogenes* is that it is able to grow at a wide range of temperatures (1 to 45°C), with optimal growth obtained between 30°C and 37°C. *Listeria* are killed at 60°C, making pasteurization an effective technique to eradicate bacteria from dairy products.

L. monocytogenes survives extreme growth conditions relatively well; from pH 4.5 to 9 and into 10% NaCl, but optimal growth occurs at neutral pH and 0.5% NaCl.

Isolation and Identification

L. monocytogenes is ubiquitous and its presence in food, environmental and clinical samples can be detected using classical or more recently developed rapid tests. Identification traditionally involved culture methods based on selective enrichment (for polycontaminated samples, such as food products) and plating on solid selective media followed by characterization of *Listeria* spp. based on colony morphology, sugar fermentation, and hemolytic properties. The characteristics of *Listeria* species identification are shown in Table 1.

For clinical samples, specific identification of *L. monocytogenes* strains can be obtained by plating on chromogenic solid media (Rapid'L.mono, BCM chromogenic agar test, CHROMagar *Listeria* test and ALOA).

These methods are the gold standard but are time-consuming and may not be suitable for testing short-lived products. This is why more rapid tests were developed based on antibodies (ELISA) or molecular techniques (PCR or DNA hybridization). These tests possess equal sensitivity and can be completed within 48h. More recently, real time PCR (RT-PCR) or nucleic acid based sequence amplification (NASBA) were developed to provide not only a measure of cell viability but also a quantitative analysis.

Serologic tests cannot be used directly for diagnosis because of an antigenic cross-reactivity between *L. monocytogenes* and other Gram-positive bacteria. However detection of anti-listeriolysin antibodies, after adsorption on streptolysin O of *Streptococcus pyogenes*, can be a good indicator of infection.

Identification Methods Used in Epidemiology

Only *L. monocytogenes* is regarded as a human pathogen, and only three of the 13 serotypes of *L. monocytogenes* are implicated in major food-borne listeriosis outbreaks. Therefore, epidemiological investigations must use techniques that are able to discern closely related *L. monocytogenes* strains in order to confirm the source of outbreak, establish patterns of transmission, or determine and monitor reservoirs of epidemic strains. Typing of *L. monocytogenes* strains is either based on phenotypic markers, such as somatic O- and flagella H-factors for serological typing, phage receptors (phage typing), and enzymes (multilocus enzyme electrophoresis). More recently, typing based on molecular variations within the bacterial genome was used. Molecular typing techniques are based on DNA hybridization, PCR, restriction digest analysis or direct sequencing of DNA. Direct sequencing of DNA is the most accurate way of comparing genetic differences or similarities. However, it is also the most expensive and time-consuming method, and currently cannot be applied to high throughput testing. Hence, methods that give a relatively accurate reflection of genetic variation as well as high sample throughput in a rapid timeframe were developed. These methods are aimed at establishing the degree of allelic variation of particular genes, which then forms the basis of measuring genetic relatedness of *Listeria* strains. Some important molecular techniques are well established and are routinely used, such as ribotyping, macrorestriction digests, pulse-field electrophoresis (PGFE), PCR-fragment length polymorphism (RFLP) or random amplified polymorphic DNA (RAPD). Other techniques such as single strand conformational polymorphism (SSCP) or multilocus sequence typing (MLST) are currently becoming established as typing sequences for *L. monocytogenes* and show great promise. In particular MLST seems to be a good candidate to replace PGFE, however there are still certain strains of *Listeria* between which it is difficult to differentiate using MLST. Laboratories are currently gathering large data sets for these methods and they will probably be considered for routine testing in the near future. Next generation sequencing will eventually overtake these techniques as well but it remains too costly for routine identification at the moment.

Inhibitory Agents and Antibiotics

Virulent *Listeria* strains are resistant to bile (up to 40%) on agar plates. This is partly due to expression of a bile salt hydrolase, encoded by the *bsh* gene (see below) and other bile tolerance genes encoded by the locus *btlA*. Classical disinfectants are active on *Listeriae*, allowing efficient treatment of surfaces in contact with food, but serum and milk reduce their bactericidal activities, emphasizing the importance placed on hygiene in food industries.

Most *Listeria* spp. are sensitive to many antibiotics such as, penicillin G, ampicillin, amoxicillin, imipenem, aminoglycosides, tetracyclines, macrolides, glycopeptides, sulfamides and chloramphenicol. A natural resistance is observed against large spectrum third generation cephalosporins (cefotaxime or cefepime), aztreonam, nalidixic acid, ofloxacin and fluoroquinolones. *Listeria*'s natural resistance to nalidixic acid, as well as growth at low temperature, is exploited to select for the pathogen, and most enrichment media contain this antibiotic. There is a discrepancy between *in vitro* resistance and the *in vivo* therapeutic efficacy of fosfomycin. This phenomenon is due to differential *in vitro-in vivo* expression of Hpt virulence factor that mediates uptake of fosfomycin in *L. monocytogenes* during infection (see below). Listeriosis treatment generally consists of penicillin G or amoxicillin and gentamicin. Trimethoprim-sulfamethoxazol association is a good alternative treatment for patients who are allergic to β-lactam antibiotics. Because of the unique intracellular life style of *L. monocytogenes* during infection of its mammalian hosts, it is impossible to employ a phage therapy approach to treat listeriosis.

In contrast, phages have been recently used in the food industry to target *Listeria*. In 2005, the virulent bacteriophage P100, which can infect and kill a majority of *L. monocytogenes* strains, was characterized and evaluated. This phage P100 was shown to be an effective and safe measure for the control of *L. monocytogenes* contamination in soft cheese and production equipment. Recently, a comprehensive study of the effect of the phages A511 and P100 on *L. monocytogenes* in various foodstuffs treated under different conditions has been completed. Both phages were highly effective in reducing or eradicating *Listeria* contamination from almost all food types tested. More recently, in July 2007, the Listex P100®, a phage-based decontamination treatment in food processing, was

approved as generally recognized as safe (GRAS) by the Food and Drug Administration (FDA) and the US Department of Agriculture (USDA).

Listeriosis

Pathophysiology

L. monocytogenes infects humans through the ingestion of contaminated food. It is able to cross the intestinal barrier and is thought to disseminate from the mesenteric lymph nodes to the spleen and the liver. The extent of intraluminal multiplication, as well as the precise location or locations at which it crosses the intestinal barrier are still debated. If not controlled properly by the immune system notably at the liver and spleen levels, *L. monocytogenes* infection may cause prolonged and asymptomatic bacteremia. It may then reach the brain or the placenta, resulting in meningitis or encephalitis mostly in immunocompromised patients, abortions in pregnant women, and generalized infections in infected neonates (granulomatosis infantiseptica).

Digestive Manifestations

Highly contaminated food products ingested by healthy individuals may result in self-limited gastroenteric symptoms. The enteric phase of the infection was previously considered to be almost always clinically silent. However, it was demonstrated that it might lead to the development of digestive symptoms such as nausea, aqueous or bloody diarrhea, abdominal pain, and fever - accounting for genuine gastroenteritis, with a rate of up to 70% of symptomatic cases, in cases of high ingested inocula. These digestive manifestations which strike healthy as well as in immunocompromised individuals are usually self-limited and resolve spontaneously.

Bacteremia

In the population at risk for invasive listeriosis, that is immunocompromised individuals, generalized infection can frequently occur after an incubation period that can be very long (10–70 days), rendering identification of the source of contamination difficult for sporadic cases. *L. monocytogenes* bacteremia might be responsible for an influenza-like febrile illness, with myalgia, arthralgia, headache and backache, but might also be clinically silent.

Pregnancy-Associated Listeriosis

The specific complications of listeriosis during pregnancy lie in the ability of *L. monocytogenes* to cross the maternofetal barrier, leading to villitis and placental abscesses, chorioamnionitis, and ultimately systemic infection of the fetus. Maternofetal listeriosis is responsible for premature labor, stillbirth, abortion, and neonatal infection with high mortality. Disseminated infection of the fetus is also called *granulomatosis infantiseptica* and is characterized by the widespread presence of microabscesses and granulomas in the liver, spleen and skin.

Infection of the Central Nervous System

In addition to its ability to cross the intestinal barrier and the maternofetal barrier in pregnant women, *L. monocytogenes* has the capacity to breach the blood–brain barrier and infect the central nervous system, resulting in both meningitis and parenchymal brain infection (encephalitis or intraparenchymal brain abscesses). Among all bacterial meningitides, *L. monocytogenes* meningitis has the highest mortality rate (22%).

Other Clinical Manifestations

In immunocompromised patients, *L. monocytogenes* has been isolated in several other clinical contexts, such as endocarditis, rare localized infections (conjunctivitis, skin infection or lymphadenitis), digestive diseases (peritonitis or cholecystitis), or hematogenous seeding (macroscopic abscesses of liver and spleen, pleuropulmonary infections, joint infection and osteomyelitis, pericarditis, myocarditis, arteritis or endophthalmitis).

Epidemiology

L. monocytogenes more commonly infects individuals with attenuated cell-mediated immunity. Populations at risk include pregnant women and neonates, adults with underlying diseases (including cancer patients, organ transplantation recipients, people with AIDS, chronic hepatic disorder, diabetes) and the elderly.

A limited geographical distribution of listeriosis is observed, as it is mainly reported from industrialized countries (Table 2) with very few reports from Africa, Asia and South America. Whether this reflects different consumption patterns, dietary habits, host susceptibility, or lack of testing facilities is not known.

L. monocytogenes has been isolated from many types of food all of which have been associated with major outbreaks, but milk and more specifically dairy products have been repeatedly involved (Table 2).

Within the species differences in virulence among strains of *L. monocytogenes* seem to exist. Epidemiological data indicate, that not all strains of *L. monocytogenes* are equally capable of causing diseases in human. Isolates of only three (1/2a, 1/2b, 4b) of the 13 serovars identified within this species are responsible for 98% of the human listeriosis cases reported. Furthermore, the major

?, undetermined.

food-borne outbreaks of listeriosis, as well the majority of sporadic cases, have been caused by serovar 4b strains suggesting that strains of this serovar may possess unique virulence properties (Table 2).

The characterization of a large number of *L. monocytogenes* strains by several molecular epidemiological tools, such as pulse-field electrophoresis (PGFE) or multilocus enzyme electrophoresis (MLEE) was able to identify three lineages within this species. These lineages correlate with serovars: lineage I includes strains of serovar 1/2a, 1/2c, 3a; lineage II comprises strains of serotypes 1/2b, 4b, 4e; and lineage III includes strains of serotypes 4a and 4c. This classification is highly robust, because it is also reproduced when using other molecular typing methods such as ribotyping, Multi Locus Sequence Typing (MLST) and DNA-array hybridization. These findings led to the idea that the three lineages are of ancient origin and the congruence of various methods highlights the genomic stability of *Listeria* species.

L. monocytogenes is a relatively rare human disease (232 cases of invasive infections in France in 2006, including 48 cases of meningitis). *L. monocytogenes* is first and foremost an animal pathogen, in which it may be responsible for sporadic cases as well as outbreaks in wild as well as domesticated animals.

Animal Models

It would be ideal to use animal species that are naturally infected by *L. monocytogenes* as model organisms to study the physiopathology of human listeriosis. This approach has not been feasible because the animals that develop the disease most similar to human listeriosis are not classical laboratory animals but rather farm animals such as sheep, cattle and goats. The common clinical features of zoonotic listeriosis are abortion, central nervous system infection, digestive disease and bacteremia. In contrast, in rat and mouse models a relatively mild infection is observed, on the other hand epidemic septicemiae are frequently observed in captive and wild colonies of guinea pigs, chinchilla or gerbils.

Moreover, it was shown that *L. monocytogenes* possesses stringent species specificity in terms of cellular invasion. This species specificity affects two major virulence factors of *L. monocytogenes*, InlA and InlB, which are able to recognize their respective receptors in humans, but not in all other species. InlA and InlB gain entry into cells by binding E-cadherin and Met, respectively (see V.B. Major virulence factor implicated in cellular life of *L. monocytogenes*). InlA does not engage mouse E-cadherin, due to a single amino acid substitution in comparison with human E-cadherin. A novel animal model was thus developed to study the role of InlA *in vivo*: it is a transgenic mouse expressing human E-cadherin in the intestinal enterocytes. In the same vein, InlB does not recognize or activate guinea pig or rabbit Met (Figure 2).

Human explants and cells remain the best system to study *Listeria* infection. For example, human explants have been successfully used to determine the mechanism by which *L. monocytogenes* interacts with the maternofetal barrier.

Caenorhabditis elegans and *Drosophila melanogaster* can be also infected by *L. monocytogenes*. Indeed, *L. monocytogenes* can establish lethal infections in adult fruit flies and larvae with extensive bacterial replication occurring before host death. Bacteria were found in the cytosol of insect phagocytic cells, and were capable of directing host cell actin polymerization. Bacterial gene products necessary for intracellular replication and cell-to-cell spread within mammalian cells were similarly found to be required within insect cells, and although *L. monocytogenes* virulence gene expression normally requires temperatures above 30°C, bacteria within insect cells were found to express virulence determinants at 25°C. Mutant strains of *Drosophila* that were compromised for innate immune responses demonstrated increased susceptibility to *L. monocytogenes* infection. Thus *Drosophila* has the potential to serve as a genetically tractable model that will facilitate the analysis of host cellular responses to *L. monocytogenes* infection. In addition,

Figure 2 Species specificity of *Listeria monocytogenes* InlA and InlB. InlA and InlB bind and induce entry of *L. monocytogenes* into human cells that express the respective cell-surface receptors, E-cadherin or Met. However, a single amino-acid change in E-cadherin (at position 16; see text) prevents InlA from binding mouse E-cadherin. InlB cannot recognize guinea pig or rabbit Met.

zebrafish larvae have been successfully infected with *L. monocytogenes*. Intravenous infection leads to the capture of bacteria by macrophages, escape from the vacuole and even instances of cell-to-cell spread and actin comet tail formation *in vivo*. Most importantly, zebrafish larvae are an excellent system for *in vivo* live imaging of infection in real time.

Infection Cycle of *L. monocytogenes* and Molecular Mechanisms of Cell Subversion

Overview of *L. monocytogenes* Infectious Cell Cycle

The ability of *L. monocytogenes* to invade and replicate within mammalian host cells involves an amazing diversity of interactions between bacterial and cellular proteins. Intriguingly, many bacterial effectors provoke normal processes in the host cell suggesting some sort of evolutionary conversion between bacterial proteins performing roles in bacteria and also having secondary functions in virulence in mammalian cells.

L. monocytogenes has the ability to infect phagocytic and non-phagocytic cells such as fibroblasts, enterocytes, hepatocytes, epithelial and endothelial cells. While entry into phagocytic cells, such as macrophages or dendritic cells is bacteria-independent, entry into non-phagocytic, e.g. epithelial cells, is mediated by the bacterium (Figure 3). Invasion involves two critical *Listeria* internalins: internalin A (InlA) and InlB that interact with E-cadherin and Met (or HGF-R, the hepatocyte growth factor receptor), respectively. Depending on the cell type, *L. monocytogenes* may use E-cadherin, Met or both receptors to internalize. Both interactions (InlB/Met, or InlA/E-cadherin) trigger intracellular signalling cascades that induce the actin polymerization required to provide the necessary force to engulf the bacteria. Internalized bacteria reside for approximately 30 min in a vacuole that is lysed by the concerted effort of the pore-forming toxin listeriolysin O (LLO) and two secreted phospholipases PlcA and PlcB. Then, bacteria are released in the cytoplasm, start to multiply and polymerize actin. The listerial surface protein, ActA, triggers polymerization of actin at one of the bacterial poles giving rise to the structure known as actin tail or actin comet. This event propels the bacterium through the cell cytosol. Actin-propelled bacteria can push the cytoplasmic membrane, generating protrusions that invade neighbouring cells. *L. monocytogenes* is therefore able to pass from one cell to another without being exposed to the external milieu, avoiding contact with circulating antibodies and other extracellular bactericidal compounds. *L. monocytogenes* then lyses the double membrane vacuole (one membrane originating from the first infected cell and the other from the second infected cell) by the action of PlcB and LLO, and a second infection cycle can begin.

Figure 3 *Listeria monocytogenes* life cycle. (a) *L. monocytogenes* induces its entry into a non-professional phagocytes via InlA or InlB. (b) Bacteria are internalized in a vacuole. (c and d) The membrane of the vacuole is disrupted by PlcA, PlcB and LLO. Bacteria reach the cytoplasm, where they multiply and polymerize actin, as observed by the presence of the characteristic actin tails induced by ActA. (e) Actin polymerization allows bacteria to pass into a neighbouring cell by forming protrusions in the plasma membrane. (f) Upon entry into the neighbouring cell, bacteria are present in a double-membrane vacuole, from which they can escape using PlcB and LLO to perpetuate the cycle.

Major Virulence Factors Implicated in the Cellular Life of *L. monocytogenes*

InlA, InlB and other internalins: InlA and InlB were the first two *L. monocytogenes* effectors described to promote host cell invasion. Both proteins are necessary and sufficient to induce bacterial entry in host cells that express their respective receptors, E-cadherin for InlA and Met for InlB. InlA and InlB are two members of the internalin family which is comprised of proteins with an N-terminal leucine rich repeat (LRR) domain composed of tandem repeats of 20–22 amino acids structured in a solenoid-like shape. Each repeat is formed by a five amino acid β -strand followed by a seven-residue loop, a five-residue 3_{10} -helix, and a second five-residue loop, adds a new turn to the LRR solenoid structure. The β -strands forms the concave face normally implicated in protein-protein interactions. The LRR domain is flanked by a cap domain corresponding to the N-terminus of the mature protein and an Ig-like interrepeat (IR) region, structurally related to immunoglobulin (Ig) domains (Figure 4). The 2001 genome sequence of *L. monocytogenes* EGDe revealed the presence of 25 internalins. There are more internalins in *L. monocytogenes* than in any other Gram-positive bacterium.

InlA Promotes L. monocytogenes Internalization by Mimicking Adherens Junctions Formation

InlA mediates invasion by interacting with cellular E-cadherin, a transmembrane protein required for the formation of a type of cell-to-cell adhesion structure called adherens junctions. The formation of the adherens junction involves the N-terminal domain (EC-1) of two E-cadherin molecules that mediate cell to cell adhesion by homophilic interactions in a Ca^{2+} dependent manner. One key residue in this interaction is Trp2, which forms an EC-1/EC-1 inter-molecular bridge. Trp2 can also insert intra-molecularly in a “closed” conformation which abrogates intermolecular interactions and hence does not allow formation of adherens junctions. The intracellular part of E-cadherin mediates the interactions of the adherens junction complex with the actin cytoskeleton. InlA also binds to the E-cadherin EC-1 domain, but through a different zone than that which is involved in E-cadherin/E-cadherin interactions. The LRR domain of InlA specifically wraps around EC-1 (Figure 5). The Pro16 residue in EC-1 is critical to the InlA/E-cadherin interaction as revealed by mutagenesis and confirmed by the structure of the InlA/E-cadherin co-crystal. Replacement of Pro16 in human E-cadherin by glutamate in mouse E-cadherin (which shows 85% identity and superposable structure with the human E-cadherin) prevents InlA from binding mouse E-cadherin and renders mice resistant to InlA-triggered bacterial infections. Despite the lack of homology between InlA and E-cadherin, InlA binding to human E-cadherin, triggers the recruitment of the proteins that form the adherens junctions complex, including β and α catenins. Similar to E-cadherin during junction formation, InlA promotes cortactin- and Arp2/3-dependent polymerization of actin. However, the actin rearrangements induced by

Listeria monocytogenes EGDc. Homologous regions are color

Figure 4 Schematic domain organisation of the 25 internalins from *L. monocytogenes* EGDc. Homologous regions are colour coded with legend provided in boxes on the right. Numbers inside boxes indicate the number of repeats. (a) Internalins can be separated in three groups by reference to their association with the bacterial surface : I, LPXTG-internalins covalently attached to the cell wall by sortase A; II, GW- and WxL-internalins non-covalently attached to the cell wall lipoteichoic acids; III, Secreted internalins. (b) InIH results from a recombination event between InIC2 and InID. Domain organisation of InIC2, InID and InIH is shown on the right, while organisation of their respective gene clusters in EGD versus EGDc is squared on the left. The C-terminal part of *inIG* is present in EGD, suggesting that whole gene is present.

Figure 5 Co-crystals InIA/E-cadherin and InIB/Met. InIA, is an 800 amino acid internalin with 15 leucine rich repeats (LRR), and hence more curved than that of InIB which is formed by 7 repeats. The LRR binding zones of the E-cadherin (EC-1) and Met (a fragment of the SEMA domain) are shown. Note that InIB interacts with Met through its LRR domain but also with its Ig-like (Ig) 1 domain (not shown). 3D Images were performed using pyMol (DeLano Scientific LLC) from the PDB structures 106S and 2UZX.

L. monocytogenes during its internalization and during junction formation as well as the role of α -catenin in these processes are not fully understood. *L. monocytogenes* entering by the InlA pathway appears as a useful tool to study the cellular signalling promoting the formation of adherens junctions. The validity of using *L. monocytogenes* as a tool for adherens junction study was confirmed by a report that identified the Rho-GTPase activating protein 10 (ARHGAP10) as essential for bacterial entry and as a novel component in the adherens junction formation.

InlB Promotes *L. monocytogenes* Internalization by Mimicking HGF, the Hepatocyte Growth Factor

InlB mediates invasion by specific interaction with Met, a receptor tyrosine kinase normally involved in cellular signalling after HGF stimulation. The extracellular domain of Met includes an N-terminal semaphorin (Sema) domain, a small PSI domain (named for its presence in plexins, semaphorins and integrins) and four immunoglobulin (Ig)-like domains. HGF binding to the Sema domain of Met triggers a cellular response involving Met autophosphorylation, as well as activation of the phosphatidylinositol 3-kinase (PI3K) and the Ras-mitogen-activated protein kinase (MAPK) pathways. HGF-induced signalling leads to diverse cellular functions such as scattering, invasion, proliferation, morphogenesis and angiogenesis. It is also implicated in a large number of human cancers, correlating closely with metastasis and poor prognosis. These tumorigenic activities occur when Met is overexpressed, or when Met signalling after ligand (HGF) contact is not downregulated. Down regulation is achieved by endocytosis and degradation of activated Met. The LRR domain and the intergenic IR region of InlB interact with the first Ig domain (Ig1) and the Sema domain of Met (Figure 5), respectively, but not at the same site as HGF. The lack of competition between InlB and HGF for Met is in perfect agreement with the finding that they bind to different zones in the receptor. After binding to InlB, Met adopts a signalling-competent conformation, which is distinct from the conformation after binding to HGF. Despite the lack of structural similarity between InlB and HGF, the different domains in Met recognized by InlB or HGF and the different conformations adopted by InlB- or HGF-activated Met, the signalling after InlB or HGF stimulation is very similar. InlB-activated Met also autophosphorylates, and induces activation of PI3K and MAPK pathways. However, differences exist in signalling after InlB, or HGF activation of Met. InlB induces stronger activation of the Ras-MAPK pathway than HGF at equimolar concentration. These differences could be explained, at least in part, by the fact that InlB can recruit other molecules that could act as co-receptors, for example gC1qR, the receptor for the globular part of the complement component C1q, or GAGs the glycosaminoglycans.

Both InlB and HGF induce actin cytoskeleton rearrangements that in the case of InlB are necessary for bacterial internalization. InlB-induced actin remodelling is mediated by the actin-nucleation complex, Arp2/3, which promotes actin nucleation and polymerization. Arp2/3 activation involves the small GTPases Rac and CDC42, and two neural WASP (N-WASP) and WAVE proteins of the Wiskott-Aldrich syndrome protein (WASP) family. Proteins of the Ena/VASP family (enabled homologue/vasodilator-stimulated-phosphoprotein family), which promote actin-filament elongation, are also involved in bacterial internalization. In addition, cofilin, which is essential for depolymerization of actin filaments, functions successively as a stimulator and a downregulator of actin rearrangements that occur during the internalization process. Remodelling of the actin cytoskeleton after HGF activation of Met is involved in cell spreading, motility and migration, and the pathway leading to actin remodelling is very similar to that induced by InlB. Both, InlB and HGF induce the clathrin-dependent internalization of Met and it has been recently described that *L. monocytogenes* hijacks the clathrin-dependent endocytic machinery to invade host cells showing that clathrin can permit the internalization of objects much larger than previously known (a bacterium is far larger than the maximal size of vesicles known to use that clathrin-dependent endocytosis). In 2011 and 2012, the precise molecular steps required for internalization downstream of either InlA or InlB-mediated bacterial uptake were characterized in detail. The process begins with recruitment of the clathrin adaptor Dab2, followed by the clathrin heavy and light chain complex, phosphorylation of clathrin heavy chain then precedes Hip1R recruitment and finally the force generated to complete internalization requires Myosin VI. In addition, a similar cellular machinery is required to form junctions between cells, which is yet another example of what can be learned about cell biological processes from *L. monocytogenes*. These data show that *L. monocytogenes* is not only a useful tool to study growth factor induced signalling but also an exceptional tool to study basic features of cellular biology. The signalling induced by InlB is presented in Figure 6.

Other Internalins Playing a Role in *L. monocytogenes* Infection

In addition to InlA and InlB, three other internalins (InlC, InlH and InlJ) interact with host cells and are involved in the infectious process. None of them however acts as an invasins.

InlC. The secreted internalin InlC is extremely abundant within infected cells to the degree that it has recently been used as a surrogate to quantify infection. The *AinlC* mutant had an increased LD₅₀ compared to the wild type illustrating that is important in infection *in vivo*. In 2010, InlC was found to play a critical role during infection by dampening the innate immune response to *L. monocytogenes*. Cells with intracellular InlC prevent NF- κ B translocation to the nucleus and dampen proinflammatory cytokines. Furthermore, another group characterized that it plays a role in cell-to-cell spread through its interaction with TUBA.

InlH. InlH has an atypical LPXTG sortase recognition motif (LPTAG). However, it is anchored to the *Listeria* cell wall through a sortase A-dependent mechanism (see below). *AinlH* mutants are attenuated in bacterial colonization of spleen and liver following oral and intravenous infection of mice. The precise role of InlH during infection remains unclear. The InlH gene belongs to the operon encoding InlG, InlH and InlE in the sequenced strain EGDe. This operon has limited synteny with the operon of other *L. monocytogenes* strains, for example, *L. monocytogenes* EGD serotype 1/2a, with *inlC2* and *inlD* instead of *inlH* (Figure 4(b)). *inlH* seems to be a fusion gene containing the internalin domain of *inlC2* and the B-repeats and the sorting signal from *inlD*. But in contrast to *AinlH*, the *AinlC2* shows no defect in virulence.

Figure 6 InlA (a) and InlB (b) induced signalling cascades after binding to E-cadherin and Met respectively.

InlJ. InlJ is a member of the LPXTG internalin family with a cysteine-containing LRR motif. The *ΔinlJ* mutant is significantly attenuated in virulence in mouse infections. However its role during infection remains elusive.

LLO and Phospholipases C. Listeriolysin O (LLO), the major virulence factor of *L. monocytogenes*, is a member of a large family of pore-forming toxins, the cholesterol dependent cytolysins (CDC). These toxins are secreted by many bacteria of different genera (e.g., *Clostridium*, *Streptococcus*, *Listeria*, *Bacillus*, and *Arcanobacterium*). Similar to other CDCs, LLO binds to the host membrane as monomer and multimerizes into large complexes composed of up to 50 subunits that insert into membrane forming pores of ~200–300 Å diameter. Unlike other members of the CDC family, LLO requires a low pH for optimal lytic activity. This property facilitates the disruption of the membrane surrounding internalized bacteria and minimizes damage to the host plasma membrane. In addition, LLO is secreted before entry of the bacteria into host cells and functions extracellularly as a potent signalling molecule that activates multiple signalling pathways. LLO induces MAPK and calcium signalling in a pore-forming-dependent manner and NF- κ B signalling in a pore-forming-independent manner by mechanisms that remain unclear. Recently it has been shown that extracellular LLO modulates host gene expression by inducing post-translational histone modifications. During early steps of infection, secreted LLO from extracellular *L. monocytogenes* induces a dramatic dephosphorylation of Ser₁₀ on H3 and deacetylation of H4. These modifications correlate with modification of the transcription levels of a subset of host genes, notably with the decreased expression of key immunity factors e.g. CXCL2, DUSP4. CXCL2 is a chemoattractant chemokine with proinflammatory function and its down-regulation could reduce the recruitment of polymorphonuclear cells, which are key players in the clearance of *L. monocytogenes* during infection. DUSP4 is usually up-regulated upon activation of the MAPK pathway as a feedback mechanism. Its LLO-dependent down-regulation might suggest down-regulation of the MAPK pathway, a mechanism commonly used by many bacteria during infection to reduce the inflammatory response. Strikingly, dephosphorylation of Ser₁₀ is a feature shared by at least two other CDC toxins that is *Clostridium perfringens* perfringolysin (PFO) and *Streptococcus pneumoniae* pneumolysin (PLY), revealing a general mechanism of epigenetic regulation used by unrelated extracellular bacteria. LLO was also found to be responsible for a global deSUMOylation event following infection. This deSUMOylation occurred due to a specific degradation of the sole E2 from the SUMOylation conjugation system, Ubc9. This event leads to more efficient infection as overexpression of SUMO prior to infection had the opposite effect.

Even though LLO is absolutely required for lysis of membrane vacuoles formed during bacterial internalization in macrophages, *L. monocytogenes* can escape from these vacuoles in the absence of LLO in several human epithelial cell lines. In addition to LLO, *L. monocytogenes* secretes two phospholipases (a phosphatidylinositol-specific phospholipase C (PI-PLC or **PlcA**) and a broad-range PLC (PC-PLC or **PlcB**)) that help the bacterium escape from the primary phagosomes and from the two-membrane vacuole resulting from cell-to-cell spread of *L. monocytogenes*. Although mutations in *plcA* or *plcB* resulted in small increases in mouse LD₅₀, deletions in both genes resulted in a 500-fold increase in LD₅₀. PlcB catalyzes the cleavage of the membrane lipid phosphatidylinositol (PI) into inositol phosphate and diacylglycerol (DAG) which activates the host protein kinases C (PKC). In the absence of LLO, PlcB activity is not only required for lysis of primary vacuoles in human epithelial cells but is also necessary for efficient cell-to-cell spread.

ActA: Actin-based bacterial propulsion. *L. monocytogenes* lyses the membrane of the vacuole and enters the host cytoplasm where it polymerizes actin at one bacterial pole thereby propelling the bacteria through the cell and into neighbouring cells. The bacterial surface protein ActA, which mediates polymerization of host actin was the first protein identified to promote actin nucleation. ActA has been an outstanding tool to understand the molecular mechanism behind actin polymerization, which is involved in numerous cellular processes e.g. cellular motility, phagocytosis, endocytosis or intracellular trafficking. ActA was shown to mimic host proteins of the WASP family (which include N-WASP and WAVE). The N-terminal region of ActA, which is essential for actin-based motility, has homology to the C-terminal region of WASP, which binds the actin-nucleation complex Arp2/3. ActA and WASP proteins function as nucleation-promoting factors (NPFs) forming multi protein-protein complexes composed by NPF, actin and the Arp2/3 complex. The Arp2/3 complex comprises seven subunits, including Arp2 and Arp3, which share structural similarity to actin and are thought to function as template for actin polymerization. The discovery of the Arp2/3 complex, which is the major component of the actin polymerization machinery, came from studies looking for ActA partners. ActA has also been useful for highlighting the function of VASP, the other main ligand of ActA. VASP binds the central proline-rich domain of ActA and promotes efficient actin-based motility by recruiting the actin-binding protein profilin, which promotes polymerization at actin-filament barbed ends. Although their mechanistic role is not fully elucidated, proteins of the Ena/VASP family are important in the formation of actin fibers, filopodia and the lamellipodial leading edge. In addition to actin polymerization, ActA was reported to play a role in bacterial internalization, a property which might depend on its capacity to bind heparan sulfate proteoglycans. However the role and the mechanism of ActA as an invasin remain to be elucidated. Another group recently characterized a role for ActA in bacterial aggregation and biofilm formation. ActA makes intramolecular bridges between bacteria. Though this property is unrelated to its ability to polymerize actin, it seems important for bacterial dissemination, in particular mutants lacking ActA are shed in the feces of the animal much more rapidly than wild-type bacteria. This likely leads to less dissemination to the environment and as such fewer new infections. ActA also seems to play a role in the stress response to ROS during *L. monocytogenes* growth in the environment. Taken together, these studies highlight another example of selection pressures in the environment and in host cells that lead to distinct but essential roles of the same protein.

Vip. Vip was identified 'in silico' as a *L. monocytogenes* specific protein by the comparison of the genome sequences of *L. monocytogenes* and that of the related non-pathogenic species *L. innocua*. Vip is a surface exposed protein anchored to the *L. monocytogenes* cell wall via its LPXTG motif and involved in bacterial internalization in several cell lines. Its cellular receptor, Gp96, a chaperone normally localized in the endoplasmic reticulum has been described to modulate the immune response by affecting the intracellular trafficking of several molecules, including Toll-like receptors (critical mediators of the innate immune response). Whether *L. monocytogenes* also affects the immune response by hijacking Gp96 remains unknown.

Auto, Ami, P60, NamA. Several autolysins from *L. monocytogenes* have been involved in virulence, including Auto, Ami, P60 and NamA. Bacterial autolysins hydrolyze distinct components of the bacterial cell wall to enable *de novo* biosynthesis of the peptidoglycan layer and are involved in various biological processes including bacterial growth, protein secretion, bacterial division, competence, or sporulation. Ami is an autolytic amidase with an N-terminal domain similar to the alanine amidase domain of the Atl autolysin of *Staphylococcus aureus* and a C-terminal GW cell wall anchoring domain. Ami is exposed at the *Listeria* surface and like other GW autolysins, the molecule is likely to be secreted and targeted to the bacterial surface via its GW domain. Ami contributes to the attachment of *L. monocytogenes* to eukaryotic cells. *Aami* mutants lacking InlA or InlB or both are five to ten times less adherent than the parental strains in various cell types. The gene encoding Auto was identified by comparison of the *L. monocytogenes* and the *L. innocua* genomes. Auto possesses an N-terminal autolysin domain and a C-terminal cell wall-anchoring GW domain. Auto is required for entry of *L. monocytogenes* into cultured non-phagocytic eukaryotic cells. The Δ auto mutant also shows reduced virulence, compared with its wild type parental strain, following inoculation of mice and guinea pigs. P60, a 60-kDa secreted autolysin, is known to be involved in cell division and is associated with invasion into several mammalian cell lines. Δ iap (the deleted gene for encoding for P60) mutants are attenuated in mouse infections. P60 was characterized as a murein hydrolase based on its homology to a repeat domain of an autolysin in *Enterococcus faecium* and the observation that P60 overexpression induces autolysis in *L. monocytogenes*. **NamA** (MurA) is another *L. monocytogenes* autolysin involved in virulence. A Δ namA mutant shows reduced bacterial virulence *in vivo*. Coordinated peptidoglycan hydrolysis by p60 and NamA activities is predicted to generate glucosaminylmuramyl dipeptide, which is known to regulate host inflammatory responses. Both p60 and NamA are secreted out of the bacterial cell in a SecA2-dependent manner (see below). SecA is responsible for general protein secretion and drives the transport of a variety of extracellular proteins in *L. monocytogenes*. SecA2 is involved in the secretion of proteins lacking a signal sequence. SecA2 homologues have also been described in other Gram-positive bacteria such as *Mycobacterium* spp. and *Streptococcus* spp. The *L. monocytogenes* Δ secA2 mutant is defective in the secretion of P60, NamA and at least 15 additional cell wall-associated or secreted proteins.

PgdA and OatA. The peptidoglycan is an essential feature of the bacterial cell wall and is an important target recognized by the innate immune system. The peptidoglycan from *L. monocytogenes* is particular as its N-acetylglucosamine residues are partially deacetylated by PgdA, a peptidoglycan N-deacetylase first identified "in silico". A Δ pgdA mutant shows increased bacterial sensitivity to host lysozyme and decreased bacterial virulence in mouse models of infection. Within macrophage vacuoles, the mutant is rapidly destroyed and induces a massive IFN- β response in a TLR2 and Nod1-dependent manner. Interestingly, *L. monocytogenes* makes use of a second peptidoglycan modification to mask the bacteria from innate immune recognition. O-acetyl modification of peptidoglycan is mediated by its O-acetyltransferase, OatA and is present on 23% of *L. monocytogenes* peptidoglycan. Upon deletion of this gene bacteria are much less virulent both *in vitro* and *in vivo* and furthermore are more susceptible to lysozyme and other antimicrobial compounds. Interestingly, a different subset of cytokines is induced by the two mutants suggesting that deacetylation by PgdA and O-acetylation by OatA play complementary roles in camouflaging *L. monocytogenes* from the innate immune response. Furthermore, the presence of deacetylase genes in other pathogenic bacteria indicates that peptidoglycan N-deacetylation could be a general mechanism used by bacteria to evade the host innate immune system.

Bsh. Bile salts are end products of cholesterol metabolism and are primarily synthesized in hepatocytes. In response to food ingestion, bile salts are released into the duodenum helping to absorb fat. In addition to this role, bile salts have antimicrobial properties acting as detergent on bacterial membranes. Some bacteria, in particular commensal bacteria, have developed the capacity to inactivate the detergent action of bile salts with a reaction catalysed by the enzyme bile salt hydrolase (Bsh). *Listeria monocytogenes* Bsh is involved in bacterial survival in the intestinal lumen and liver. Deletion of *bsh* results in decreased resistance to bile *in vitro*, and reduced virulence in mice and guinea pigs models. The *bsh* gene is positively regulated by PrfA, the transcriptional activator of known *L. monocytogenes* virulence genes, confirming the role of Bsh as virulence factor involved in intestinal and hepatic phases of listeriosis.

Hpt. Host cell hexose phosphates can be used by *L. monocytogenes* as a carbon source allowing rapid bacterial intracellular growth. Hexose phosphate uptake is mediated by Hpt, a bacterial homologue of the mammalian translocase for glucose-6-phosphate from the cytosol into the endoplasmic reticulum in the final step of gluconeogenesis and glycogenolysis. The master regulator of virulence in *L. monocytogenes*, PrfA, regulates the expression of the Hpt permease. A Δ hpt mutant is impaired in intracytosolic proliferation and attenuated in virulence in mice. Hpt is another example of *Listeria* mimicry of eukaryotic host cells physiological mechanisms. Hpt is upregulated inside cells and allows for the uptake of the antibiotic fosfomycin that can attack intracellular bacteria expressing Hpt (see above section III E).

FbpA. FbpA (fibronectin binding protein) is required for intestinal and liver colonization in mouse models of infection. FbpA binds to human fibronectin *in vitro* and increases adherence of wild-type *L. monocytogenes* to cultured epithelial cells in the presence of exogenous fibronectin. FbpA lacks a conventional secretion/anchoring signal and is exported to the bacterial surface via SecA2.

MnSOD. Superoxide dismutases (SODs) are enzymes that protect organisms from reactive oxygen species (ROS) which are major mediators of microbicidal activity in phagocytic cells. *L. monocytogenes* express one SOD, (MnSOD) which can be phosphorylated on serine and threonine residues in the bacterial cytoplasm. These phosphorylations result in decrease of SOD activity. The non-phosphorylated form of MnSOD is more active than the phosphorylated form and can be secreted, via the SecA2 pathway, in culture supernatants or in infected cells, where it becomes phosphorylated. A Δ sod deletion mutant is impaired in survival within macrophages and is dramatically attenuated in mice, showing that the capacity to counteract ROS is an essential component of *L. monocytogenes* virulence. MnSOD was the first example of a bacterial SOD post-translationally controlled by phosphorylation, potentially highlighting a possible new host innate mechanism to counteract a virulence factor.

LntA. A new class of *L. monocytogenes* virulence factors was discovered thanks to comparative genomics. The so-called "nucleomodulins" are proteins which are secreted from the invading bacteria and subsequently translocate to the nucleus to mediate their effects on host-gene transcription. *Listeria* nuclear-targeted protein A or LntA was also discovered based on its absence in *L. innocua*. When expressed in mammalian cells, it translocates to heterochromatin rich regions and it interacts with a repressor of chromatin, BAHDI. Bacteria that lack the protein are less virulent *in vivo* and paradoxically bacteria that overexpress the protein are also impaired in virulence. This is due to a temporally controlled tuning of interferon signaling which if deregulated by the absence or untimely overabundance of the protein leads to less efficient infection. It is likely that other secreted factors of *L. monocytogenes* could also bring about changes in gene expression that could have a long-term effect on host cell memory.

Regulation of Virulence Factors

L. monocytogenes is a facultative intracellular pathogen that can live both inside and outside its host. This bacterium has therefore evolved sophisticated regulatory mechanisms to ensure that virulence factors are optimally expressed when they are required.

PrfA : A Thermosensing Regulation

The majority of virulence proteins that have been identified in *L. monocytogenes* are under the control of a the transcriptional regulator, PrfA, which itself is tightly regulated by environmental conditions (Figure 7).

PrfA is synthesized from two transcripts: a monocistronic transcript driven by two promoters (P_{1-prfA} and P_{2-prfA}) situated in the *plcA-prfA* intergenic region, and a *plcA-prfA* bicistronic transcript driven by P_{plcA} promoter (Figure 7). During exponential growth, *prfA* is primarily transcribed as a bicistronic mRNA. By contrast, during stationary phase, a monocistronic mRNA is produced.

Figure 7 The PrfA regulator. Mechanism that controls the thermoregulated expression of PrfA. At low temperature ($\geq 30^{\circ}\text{C}$), a secondary structure forms in the untranslated region of *prfA*, and this prevents ribosome binding and therefore expression of PrfA. At high temperature ($\geq 37^{\circ}\text{C}$), melting of the *prfA* untranslated region allows ribosome to bind Shine-Dalgarno sequence (SD), and PrfA expression occur. PrfA interacts with PrfA-boxes (green squares) situated upstream of regulated genes (yellow arrows).

Similar to many other pathogens, *L. monocytogenes* can sense various conditions in the mammalian host and respond by expressing virulence genes. $P1_{prfA}$ is a σ^A vegetative promoter leading to a low level of *prfA* mRNAs synthesis during normal bacterial growth. The 5' untranslated region (UTR) of these constitutive transcripts forms a secondary structure that acts as a thermosensor. At low temperatures ($<30^{\circ}\text{C}$), the secondary structure masks the ribosome-binding site and prevents the translation of the downstream *prfA* message. However, at mammalian host temperature (37°C), this structure partially melts to expose the ribosome-binding site, thereby allowing translation to occur (Figure 7). Indeed, the PrfA protein is not produced at low temperature even though monocistronic *prfA* transcripts are present. Thermoregulation of *prfA* translation provides an elegant explanation for restricting costly virulence factor production in the environment, and for mediating rapid synthesis of PrfA from a pool of untranslated transcripts as soon as the pathogen invades a warm-blooded host.

$P2_{prfA}$ is situated downstream from $P1_{prfA}$ and is regulated by both α^A and the stress-responsive alternative sigma factor σ^B . σ^B -dependent $P2_{prfA}$ occurs during the stationary phase.

The role of $P1_{prfA}$ and $P2_{prfA}$ is to provide basal levels of *prfA* transcripts, ensuring that a minimal amount of PrfA protein is continuously present in the bacterial cytosol. This basal amount appears to be sufficient to stimulate the PrfA-hypersensitive *hly* (coding for LLO) and *plcA* genes and to mediate escape from the phagocytic vacuole, but not to stimulate other genes requiring a more intense PrfA stimulus, such as those involved in cell-to-cell spread.

The P_{plcA} promoter is PrfA-dependent, so that through the *plcA-prfA* bicistronic transcript, PrfA can stimulate its own synthesis by positive feedback.

Three groups of genes have been identified as PrfA-dependant by a transcriptomic approach. Group I comprises twelve genes including ten major virulence genes (*inlA*, *inlB*, *inlC*, *htp*, *plcA*, *hly*, *mpl*, *actA*, *plcB* and *orfX*), *lmo2219* and *lmo0788*. These genes are strongly induced in active-PrfA background and during intracellular infection. A putative PrfA box precedes these genes. They are organized into several transcriptional units, of which four are clustered in the pathogenicity island (LIPI-1) essential for *L. monocytogenes* virulence (Figure 7). Group II comprises eight genes encoding a putative sugar transport system that is negatively regulated by PrfA, indicating that PrfA can also act as a repressor. Only one of them (*lmo0278*) is preceded by a putative PrfA box and

the remaining seven genes (*lmo0178-lmo0184*) are organized in an operon. Group III comprises fifty-three PrfA-upregulated genes of which only two (*lmo0596* and *bsh*) are preceded by a putative PrfA box.

VirR : Global Regulation of Surface Component Modification

VirR is the response regulator of the two-component system VirR/VirS. Deletion of *virR* decreases virulence in mice as well as invasion in cell-culture experiments. By comparing the transcriptomes of *virR* deletion versus wild type bacteria, twelve genes seem to be regulated by VirR. These genes include the *dlt*-operon, involved in modification of cell wall teichoic and lipoteichoic acid, that are both also important for *L. monocytogenes* virulence. Another VirR-regulated gene is homologous to *Staphylococcus aureus mprF*, which encodes a protein that modifies membrane phosphatidyl glycerol with L-lysine and is involved in resistance to human defensins.

VirR thus appears to control virulence by a global regulation of surface component modification. These modifications may affect interactions with host cells, in particular components of the innate immune system, such as Toll-like receptors. Interestingly, although controlling the same set of genes as VirR, the cognate histidine kinase of VirR, VirS was not shown to be essential for virulence. Furthermore, VirR can be activated independently of VirS. Finally, as is the case of PrfA, VirR-regulated promoters were shown to possess a DNA-binding consensus site (CTNACAwwwTGTNAG), and specific interaction between this consensus sequence and purified VirR protein has been demonstrated.

Sigma B

L. monocytogenes is predicted to contain only five sigma factors in comparison to 18 in *B. subtilis* and 13 in *Mycobacterium tuberculosis*. The *L. monocytogenes* sigma factors are similar to *B. subtilis* SigA, SigB, SigH, SigL (RpoN, sigma 54) and ECF-type sigma factors.

The alternative sigma factor sigma B modulates the stress response of several Gram-positive bacteria, including *Bacillus subtilis* and the food-borne human pathogens *Bacillus cereus*, *L. monocytogenes* and *Staphylococcus aureus*. In all these bacteria, sigma B is responsible for the transcription of genes that can confer protection against adverse conditions. Upon exposure to stress a regulatory cascade is triggered leading to the activation of sigma B and subsequently to transcription of sigma B-regulated genes. In *L. monocytogenes*, sigma B plays a role in growth and survival at low temperatures, acidic conditions and to the stress of the intracellular environment.

The deletion of *sigB*, however, has limited effects on virulence, as shown in animal models, even though several listerial virulence factors are under the control of sigma B. Interestingly, the *bsh* gene encoding the bile salt hydrolase and two genes from the internalin family, which contribute to bacterial entry are partially sigma B-dependent and also PrfA-regulated. The central role of sigma B in the regulatory network of the bacterium is further illustrated by the fact that sigma B can control other important regulatory proteins like the RNA-binding protein Hfq in *L. monocytogenes*. Hfq is thought to play a crucial role in the post-transcriptional regulation of gene expression by small non-coding RNAs and the dependence of this regulator on sigma B adds another level of complexity to the function of sigma B in *L. monocytogenes*.

Genomics and Post Genomics

Genome Sequencing of *Listeria monocytogenes* EGDe and *Listeria innocua* CLIP11262

In 2001, the determination of the complete genome of the pathogen *L. monocytogenes* (strain EGDe) and that of the closely related non-pathogenic species *L. innocua* (strain CLIP11262) were achieved by a consortium of 10 European laboratories. In 2004, The Technical Institute of Genomic Research (TIGR) determined the sequence of another *L. monocytogenes* strain (*L. monocytogenes* serovar 4b, strain F2365). Currently, ten *Listeria* species have been identified and sequenced (*L. monocytogenes*, *L. innocua*, *L. ivanovii*, *L. seeligeri*, *L. welshimeri*, *L. grayi*, *L. marthii*, *L. rocourtiae*, *L. weihenstephanensis* and *L. fleischmannii*) two of which are pathogenic: *L. monocytogenes* and *L. ivanovii* (for ruminants). The availability of these different genome sequences of *Listeria* spp. paves the way for comparative genomics studies and the identification of unknown virulence factors. There are currently thirty-nine complete genome sequences of *Listeria monocytogenes*, with more being sequenced daily, including the recent sequencing of the frequently used strain EGDe.

The *L. monocytogenes* (strain EGDe) genome is 2.9 Mb long with an average G+C content of 39% and 2853 predicted protein-coding genes. The *L. innocua* genome is 3.0 Mb with an average G+C content of 37% and 2981 predicted protein-coding genes. Comparative genome analysis identified that 2587 of 2853 genes of *L. monocytogenes* EDGe possess an orthologous gene in the *L. innocua* genome.

The most striking feature of these genomes is that they encode an exceptionally large number of surface proteins (4.7% of all predicted genes of *L. monocytogenes* EGDe), especially proteins that belong to the internalin family (Figure 4). The ability of *Listeria* spp. to colonize and grow in a broad range of ecosystems correlates with an abundance of transport proteins (11.6% of all predicted genes of *L. monocytogenes* EGDe), in particular proteins dedicated to carbohydrate transport mediated by phosphoenolpyruvate-dependant phosphotransferases. Furthermore the extensive regulatory repertoire (7.3% of all predicted genes of *L. monocytogenes*

EGDe) identified correlates with the varied environmental conditions faced by *L. monocytogenes*. This high proportion of regulatory genes is second only to that of *Pseudomonas aeruginosa*, another ubiquitous pathogen.

In contrast to many other bacterial genomes, the *L. monocytogenes* genome contains only three copies of one insertion sequence and that of *L. innocua* does not contain any. Both genomes contain bacteriophages, but these do not seem to play a major role in acquisition of virulence genes as has been shown for other bacteria such as pathogenic *E. coli*. A perfect conservation in the order and in the relative orientation of orthologous genes was observed between *L. monocytogenes* EGDe and *L. innocua* genomes. This co-linear organization may be related to the low occurrence of insertion sequences. Surprisingly, comparison of the two *Listeria* genomes with related bacterial genomes that have low G+C, such as *Bacillus subtilis* or *Staphylococcus aureus* reveals a similar organization, indicating that genomes of this group of bacteria are particularly stable.

Sequence analysis of the two *Listeria* genomes revealed a close relationship to *B. subtilis*, suggesting a common origin of the three species. *L. monocytogenes* subsequently acquired multiple non-contiguous DNA fragments, including the virulence locus LIPI-1 (Figure 7), which is absent in the genome of *L. innocua* and was probably lost.

Post Genomic Studies

Following the sequencing of *L. monocytogenes* strain EGDe, several post genomic studies, based on genome comparison, have been performed to identify new virulence mechanisms and new genetic features. In 2012, a new study generated genome wide Transcription Start Site (TSS) maps of *L. monocytogenes* and *L. innocua* coupled with a browser to compare transcriptomic and RNA-seq data in a variety of conditions to assess differential regulation of genes and allow direct comparison between the non-coding genome of the two strains.

This approach yielded highly interesting comparisons between the genomes, and more specifically the identification of noncoding RNAs (ncRNAs) in *L. monocytogenes*. Previously, computer-based method analysis of the intergenic regions of the EGDe strain led to the identification of twelve ncRNAs. Among these 12 new ncRNAs, nine ncRNAs named *Rli* genes (*RliA* to *RliI*) appear to be specific to the genus *Listeria* with no homologous counterparts detected in other bacterial genomes. *RliA*, *C*, *F* and *G* are present in *L. monocytogenes* and absent in *L. ivanovii* and in non-pathogenic *L. innocua*. *rliB* is duplicated in *L. ivanovii*, an ovine pathogen, but is absent in *L. innocua*. As with protein coding genes, ncRNAs absent in *L. innocua* species might be involved in infection. The four other *Rli* family genes (*RliD*, *E*, *H* and *I*) were identified in all *Listeria* species, suggesting these ncRNAs genes would control non-infection related functions. Furthermore, a novel computational approach was developed to search mRNA targets of ncRNAs in bacteria. mRNA targets were predicted for five (*RliB*, *D*, *E*, *H* and *I*) of the nine *Rli* ncRNAs. Finally, *in vitro* experiments demonstrate pairing between ncRNAs and each predicted mRNA target suggesting a role for these 'new regulatory factors'.

Post genomic studies were also performed to investigate the genetic diversity of *L. monocytogenes* strains with varying virulence potential. An epidemic serovar 4b strain was partially sequenced and compared with the complete genome of the non-epidemic *L. monocytogenes* EGDe serovar 1/2a. This approach identified unexpected genetic divergences between the two strains, as about 8% of the sequences were serovar 4b specific. These sequences included seven genes coding for surface proteins with the LPXTG motif, six transport proteins, three transcriptional regulators, one phosphotransferase system component and twenty-six unknown proteins. All of these newly identified proteins might be important to different steps of the infectious process. Furthermore, the comparison of the gene content of 113 *Listeria* strains was performed by using an array containing the flexible part of the sequenced *Listeria* genomes. Hybridization results showed that all identified virulence factors were present in the ninety-three *L. monocytogenes* strains tested. However, distinct patterns of the presence or absence of other genes were identified among different *L. monocytogenes* serovar and *Listeria* species.

The genome analysis of *L. monocytogenes* EGDe revealed the presence of forty-one genes encoding surface proteins bearing an LPXTG motif, two surface proteins containing an NXZTN motif and two sortases (*SrtA* and *SrtB*). Sortases are enzymes that anchor surface proteins to the cell wall of Gram-positive bacteria by cleaving a sorting motif located in the C-terminus of the protein substrate. The best-characterized motif is LPXTG, which is cleaved between the T and G residues. Non-gel proteomic approaches identified a total of thirteen LPXTG-containing proteins anchored in the peptidoglycan by *SrtA*, six of which (*InlA*, *InlG*, *InlH*, *Lmo1413*, *Lmo1666* and *Lmo2085*) have no ortholog in the closely related non-pathogenic *L. innocua*. Two surface proteins, *Lmo2185* and *Lmo2186* were identified only when *SrtB* was active. The analysis of the peptides identified in these proteins suggests that *SrtB* of *L. monocytogenes* may recognize two different sorting motifs, NXZTN and NPKXZ. A mutant Δ *srtA* is strongly attenuated in virulence, while no impact in virulence could be detected with the Δ *srtB* mutant. In contrast the *SrtB* ortholog in *Staphylococcus aureus* is involved in heme capture and virulence.

Another example of the efficiency of comparative genome studies was the discovery of an auxiliary protein secretion system (*SecA2*) present in *L. monocytogenes* and eight other Gram-positive pathogens that cause severe or lethal infection in humans. In *L. monocytogenes*, a proteomic approach identified seventeen *SecA2*-dependent secreted and surface proteins. The two most abundant of these proteins, the p60 and N-acetylmuramidase (*NamA*), hydrolyze bacterial peptidoglycan and contribute to host colonization. Coordinated peptidoglycan hydrolysis by p60 and *NamA* activity generates bacterial cell wall fragments. Thus, *SecA2*-dependent secretion may promote release of muramyl peptides that may modify host inflammatory responses and subvert host pattern recognition.

Taken together post-genomic comparative studies are paving the way to discovery of novel virulence factors and may help to understand pathogen evolution.

Conclusion and Perspectives

The *Listeria* genus is composed of six species among which *L. monocytogenes* is the only human pathogen. This food-born pathogen is responsible for listeriosis after ingestion of contaminated food. Listeriosis is characterized by a high mortality rate (>30%) especially in susceptible populations (immunocompromised patients, pregnant women, and the elderly). These reasons explain the absolute requirement for *L. monocytogenes* detection in food products and its eradication as soon as possible in food storage and processing.

L. monocytogenes is one of the most well-studied bacterial pathogens. This facultative intracellular bacterium has in the last twenty years become a paradigm to study host-pathogen interactions and bacterial adaptation to the mammalian host. Analysis of *L. monocytogenes* has provided considerable insight into how bacteria invade cells, move intracellularly, and disseminate in tissues, as well as tools to address fundamental processes in cellular biology. Thanks to its capacity to provoke cell-mediated immunity, *L. monocytogenes* was also used as an efficient tool to study the induction of the T-cell immune response, and this bacterium is being developed as a vaccine vector for antigen delivery, with potential a potential impact in infection and cancer. Continued research into the molecular biology of *Listeria* infection coupled with the availability of the complete genome sequences of *L. monocytogenes* and of the related non-pathogenic *L. innocua*, will continue to be fruitful to both basic microbiology and cellular biology.

EDITOR-IN-CHIEF

Thomas (Tom) Schmidt is a microbial physiologist and ecologist who studies diverse microbes and microbial communities. Tom received a PhD from The Ohio State University and conducted postdoctoral research at Scripps Institute of Oceanography and Indiana University. He spent much of his career studying the ecology of microbes in soil that are responsible for the exchange of greenhouse gases with the atmosphere. More recently, he joined the University of Michigan and focused his research on the human microbiome. His joint appointment in the Departments of Internal Medicine and Ecology & Evolutionary Biology reflects his expertise in applying ecological and evolutionary principles to understand the functioning of complex microbial communities.

Tom is a fellow of the American Academy for Microbiology and was director of the Marine Biological Laboratory's Microbial Diversity Course in Woods Hole. Through that course and in his laboratory, he has helped numerous scientists incorporate molecular approaches into traditional strategies for studying the microbial world. He currently teaches a university course that merges his research and teaching goals by engaging students in a coordinated study of the effects of diet on the gut microbiome, and he directs a graduate program that combines laboratory sciences and modeling. Tom was a section editor for previous editions of the *Encyclopedia of Microbiology* and was delighted to assume the role as editor-in-chief to help bring the microbial world to an expanding audience.

EDITORIAL BOARD

Bianca Brahamsha is a research microbiologist at Scripps Institution of Oceanography at the University of California, San Diego. She was a biology and history major at Goucher College, earned her PhD in microbiology at Cornell University, and carried out postdoctoral work in molecular genetics as an American Cancer Society fellow at the University of Chicago. Her research interests have centered on bacterial motility, the genetics and physiology of marine cyanobacteria, and on the interactions between cyanobacteria and their eukaryotic predators.

James (Jim) Brown was born in Atlanta, Georgia, and lived in Dade City (Florida), Bloomington (Indiana), Lima (Peru), and Muncie (Indiana) while growing up. From the beginning, he had an intense interest in nature, including anything found in the woods, rivers, beach or ocean that were always nearby.

Jim attended Ball State University beginning in 1976. A single lecture on microbial diversity in a general microbiology class, followed by the announcement of the discovery of the Archaea (George Fox and Carl Woese, 1977), sparked his lasting interest in microbiology. This led to undergraduate research examining *Beggiatoa* in a sulfur spring in French Lick, Indiana. After receiving his BS in biology in 1980, he joined the graduate program in microbiology at Miami University, where he worked on plant tissue culture mRNAs with Prof. Ronald Treick. After obtaining an MS degree in 1982, he moved to the MCD Biology Program at The Ohio State University to work on the molecular biology of methanogenic Archaea in the Department of Microbiology with Prof. John Reeve. While there, Jim worked on polyadenylation of mRNAs, RNA polymerase, and promoters in Archaea, and received his PhD in 1988. Jim then went to Indiana University for 5 years of postdoctoral work in Prof. Norman Pace's lab on the comparative analysis of the structure of a bacterial ribozyme, RNase P.

In January of 1994, Jim started as an assistant professor in the Department of Microbiology and moved to North Carolina State University. Research in Jim's lab focused on the comparative sequence and biochemical analysis of RNA, and in particular RNase P in Archaea. Students in the Brown lab developed a high-resolution model for the structure of this RNA, how it changed over the diversification of the Archaea, the protein subunits associated with the RNA, and how they contribute to the function of the holoenzyme. Jim developed, teaches, and wrote the textbook for a senior-level undergraduate lab course in microbial diversity. Jim is now Professor Emeritus in the Department of Biological Sciences at NC State University.

Jim has a son and two daughters, and is married to Melanie Lee-Brown, professor of biology and director of Research and Creative Endeavors at Guilford College. For fun, Jim enjoys skin and scuba diving, driving (i.e., working on) his 1968 Lotus Super Seven, and restoring vintage racing bicycles. Jim and Melanie have been renovating an abandoned fishing lodge on North Caicos Island (Turks and Caicos Islands, BWI), which will be reopened soon as a bed and breakfast.

Larry Forney is a university distinguished professor and a member of the American Academy of Microbiology with academic appointments in the Department of Biological Sciences and Bioinformatics and Computational Biology at the University of Idaho. Dr. Forney is an evolutionary ecologist who conducts research on the complex array of factors that influence the function, composition, structure, and temporal dynamics of bacterial communities in a wide array of habitats. In recent years he has largely focused on the community ecology of the human vagina across a woman's lifetime with an eye on understanding how changes in community structure and function affect a woman's risk to bacterial vaginosis, sexually transmitted infections, and pre-term birth, and how host factors shape these communities. His research extends to understanding the mutation-selection processes that govern the occurrence and persistence of genetic diversity of bacterial populations in spatially structured environments such as microbial biofilms and porous media. These studies have shown that spatial structure creates condi-

tions in which mutation frequencies are high and selective sweeps are protracted, which leads to extraordinary within species diversity that increases the resilience of populations to environmental changes.

Robert Haselkorn was the F. L. Pritzker distinguished service professor of molecular genetics and cell biology at the University of Chicago, retiring several years ago. He was an undergraduate at Princeton, a graduate student at Harvard, and a postdoctorate in Cambridge, England. He started his teaching career at Chicago in 1961 in biophysics, extending later to microbiology, biochemistry, and chemistry. His research interests have centered on heterocyst differentiation in nitrogen-fixing cyanobacteria, in bacterial genomics, and in the enzyme acetyl-CoA carboxylase in plants, parasites, and people. He is a member of the National Academy of Sciences, a fellow of the American Academy of Arts and Sciences, and a member of the American Philosophical Society. Among other external activities he was a founder and adviser for 20 years to the International Center for Genetic Engineering and Biotechnology, located in Italy and India. For the past 15 years Haselkorn and his wife Margot have been working on selection and supporting a speaker for the Haselkorn Lecture at the University of Chicago,

an award they have endowed. Many of the Haselkorn Lecturers have been Nobel Prize winners or will be soon.

Jennie C. Hunter-Cevera received her PhD from Rutgers University in 1978 (microbial physiology and biochemistry), an MS in microbial ecology in 1972, and a BS in biology from West Virginia University in 1970. She is the founder of Hunter and Associates, a consulting firm focusing on finding integrative solutions to complex problems involving sustainability in the life sciences arena. From July of 2009 to August 2012, she was the executive vice president of Discovery and Analytical Sciences (DAS), Corporate Development and Government Relations. She has 22 years of experience in the pharmaceutical and biotechnology industries (E. R. Squibb and Sons, Cetus Corporation, GeoBiotics, and Universal Foods). She was the co-founder of The Biotic Network and Blue-Sky Laboratory that contracted with biotechnology and pharmaceutical companies on basic and applied natural product research. Dr. Hunter-Cevera was an

employee for 5 years with the Department of Energy as the head of the Lawrence Berkeley National Laboratory's Center for Environmental Biotechnology. She worked in academia for 10 years as the president of the University of Maryland Biotechnology Institute and 2 years as the Interim Provost of Mount St. Mary's University. She also served as project manager for UC Davis's CIFAR (Center for Industrial Food and Agricultural Research). She has published many papers and chapters, and served as senior editor of the *Journal of Industrial Microbiology and Biotechnology* for 10 years. She is a co-section head of microbiology for Faculty of 1000. She holds 15 patents and specializes in areas of screen design for the discovery of natural compounds in the area of human therapeutics, biodefense, sustainable agriculture, bioremediation, and biocatalysis for industrial processes in the food and clothing industries.

While in Maryland, she served as a member of the Executive Committee for Governor Ehrlich's transition team, his Committee on science, technology, engineering, and maths, and was the Technology Representative for Governor Glendenning on the Southern Governor's Association, and she served on the Technology Economic Development Corporation, TEDCO (Board of Directors for 4 years and was Chair for 2 years). Dr. Hunter-Cevera also served on the Advisory Board for the Maryland Industrial Partnerships, the MDBio's Board of Directors, and the MDBio Foundation for 10 years and on the BioIT Coalition for 5 years. She served as an Entremed Board Member for 10 years and served on the Executive Committee for 2 years. She was a board member for Patients with Power, a software company that designs programs for cancer patients to make the best decisions for their treatments. Jennie also served as acting secretary for Maryland's Higher Education Commission in 2015.

She is a member of several professional societies and has served as president of the Society for Industrial Microbiology, the International Marine Biotechnology Association, and the United States Federation of Culture Collections. Dr. Hunter has served on many national committees and commissions and was Chair of the National Research Council's Committee on Large Scale Production of Biofuels from Algae. She also chaired two other NRC Committees: Standing Committee on DOD's Translational Medicine and the DOE's Genome to Life for Biofuels.

She is the recipient of several awards and honors including Maryland's Top 50 Influential People (2007, 2009) and Maryland's Top 100 Women (2003, 2006, 2009), American Society for Microbiology's Porter Award for distinguished research in microbial systematics and taxonomy, elected as a SIM fellow, a member of the ASM Academy of Microbiology, and an AAAS fellow. She is also a WVU Distinguished Alumni Awardee and Nath lecturer and served as an entrepreneurial coach for the UNC Executive MBA program. She was awarded an Honorary Doctorate from West Virginia University, May 2013, and the Rutgers Cook College Dennis M. Fenton Distinguished Graduate Alumni Award in 2014.

She currently serves on the International Advisory Council for Brazil's Fundação Dom Cabral which is a world-class Brazilian business school that develops strategic thinking skills of executives, entrepreneurs, and public-sector managers. In addition, Jennie served 6 years on the Edison Awards Steering Committee and currently serves on the Edison Awards Advisory Board.

Stanley Maloy is a professor of microbiology and associate vice president for research and innovation at San Diego State University. Stanley's research has focused on bacterial and phage genetics and physiology, evolution of infectious diseases, and development of antimicrobials and vaccines. In addition, he has consulted with large and small companies in multiple sectors, played a role in starting several Biotech companies, and served leadership roles in multiple start-up companies.

Dr. McCormick earned her PhD in microbiology in the topic area of intestinal ecology, and completed postdoctoral training at Harvard Medical School. She remained on the faculty of Harvard Medical School where she was an associate professor of pediatric gastroenterology, and director of research for the Mucosal Immunology and Biology Research Center at Massachusetts General Hospital. In 2008, she joined the University of Massachusetts Medical School where she is professor and vice chair of the Department of Microbiology and Physiological Systems. Dr. McCormick is also the founding executive director of the University of Massachusetts Center for Microbiome Research, which she established in 2014. Dr. McCormick is one of the original pioneers in the field now known as cellular microbiology. Her work provided the first evidence that epithelial cells in response to pathogen contact orchestrate a pro-inflammatory program, which recruits inflammatory cells. Dr. McCormick has since identified new, previously

unidentified and unexpected virulence mechanisms that are key to the inflammatory response, leading to both novel biological principles of host-microbe interactions and therapeutic intervention strategies for the treatment inflammatory bowel disease, and cancer. Her work continues to identify novel ways in which microbes interact with the intestinal epithelium, publishing over 100 original research papers and opinion pieces in this area. Dr. McCormick is an elected fellow of the American Academy of Microbiology, is on the Board of Editors for *Gastroenterology*, and *Gut Microbes*, and serves as a member of four Editorial Review Boards.

Dr. Mobley received his BS degree in biology from Emory University in 1975 and his PhD degree in microbiology and immunology from University of Louisville in 1981. He conducted postdoctoral training in biological chemistry and then bacterial genetics in the Center for Vaccine Development at the University of Maryland School of Medicine. He served on the faculty at the University of Maryland School of Medicine from 1984 until 2004 in the Division of Infectious Diseases (1984–97) and then the Department of Microbiology and Immunology (1997–2004) where he led the graduate program. During that time, he held a joint appointment in the Department of Biochemistry and Molecular Biology and trained graduate students in that program. In 2004, Mobley moved to the University of Michigan to chair the Department of Microbiology and Immunology and was installed as the inaugural Frederick G. Novy Collegiate Professor of Microbiology and Immunology.

Dr. Mobley's research interests focus on the molecular mechanisms of bacterial pathogenesis and on the fundamental basic research that will lay the groundwork for future therapeutics and vaccines. His lab studies virulence mechanisms of uropathogenic *Escherichia coli* and *Proteus mirabilis* that cause uncomplicated and complicated urinary tract infections, respectively, and, in the recent past, *Helicobacter pylori* that causes gastritis and peptic ulcer disease. For *E. coli* and *Proteus mirabilis*, his lab is focused on identifying surface-exposed proteins that are both synthesized by the bacteria during a urinary tract infection and conserved among uropathogenic *E. coli* and *Proteus* strains. Using these conserved antigens, his lab is determining the efficacy of candidate proteins as components of a multivalent subunit vaccine to protect against urinary tract infection.

Dr. Mobley is a fellow of the American Academy of Microbiology and a fellow of the American Association for the Advancement of Science and a member and past president of the Association of Medical School Microbiology & Immunology Chairs. He was the recipient of the inaugural University of Michigan Postdoctoral Association Excellence in Mentorship Award in 2012. He is a member of the editorial review boards of *Infection and Immunity* and *Microbiology Spectrum* and has served as a study section member for the National Institutes of Health. Dr. Mobley was awarded and named a distinguished university professor in 2015. This is the University's most prestigious professorship established to recognize senior faculty with exceptional scholarly achievements, national and international reputations for academic excellence, and superior records of teaching, mentoring, and service.

Dr. Mobley has published 255 peer-reviewed articles which have been cited in the literature over 18,000 times as of June 2019, as well as 49 book chapters and 5 books. He has trained 29 PhD students and 38 postdoctoral fellows, and has delivered 232 invited lectures in 21 countries.

Carlos Pedrós-Alió graduated in biology at the Autonomous University of Barcelona and got his PhD in bacteriology at the University of Wisconsin–Madison. After a postdoctoral stay at the Autonomous University he became an assistant professor of microbiology. He moved to the Marine Sciences Institute (CSIC, Barcelona) in 1989 where he was a research professor since 2000. In 2016 he moved to the National Center for Biotechnology (CSIC, Madrid). Dr. Pedrós-Alió's interest is to understand the ecology of aquatic microorganisms. Around 2005 he started to use genomics as a tool to generate hypotheses that could later be tested experimentally. He also likes to study extreme environments such as hypersaline systems, thermal springs, or polar waters. Another interest is in finding the mechanisms maintaining a large number of rare bacteria in aquatic ecosystems. He is also interested in outreach, relationships between art and science, biology of spirituality, fiction writing, and birding.

PREFACE

As with previous editions of the *Encyclopedia of Microbiology*, the 4th edition takes on the challenge of providing a contemporary overview of microbes—the most abundant and diverse forms of life on Earth. These single-celled organisms were the first life forms to inhabit Earth and they transformed the planet and its atmosphere. They continue to maintain Earth's atmosphere, drive essential processes in terrestrial and aquatic ecosystems, and form intimate relationships with all plants and animals. Microbes can reproduce by doubling every 20 minutes or can remain dormant for many thousands of years. They colonize every known habitat on Earth, accounting for approximately half of the living biomass on our planet. Microbes also cause the most devastating diseases known to humans and are winning the antibiotic war we wage against them. Yet, we cannot live without microbes as symbionts of humans and drivers of Earth's biosphere.

Despite the central roles of microbes, we are only just becoming aware of our limited knowledge of interactions among microbes, other organisms, and the environment. Molecular techniques continue to lead a revolution in our understanding of microbial diversity and function, with the new “big data” sciences of genomics, transcriptomics, proteomics, and metabolomics now being applied to communities of microbes. These techniques provide the ability to identify and study complex communities of microbes in diverse environments including the human gut, forest soil, water-treatment biofilters, and the open ocean.

Given the remarkable physiological and phylogenetic diversity of microbes, their capacity for rapid evolution, and the pivotal role of host-associated and environmental microbiomes, it is difficult, if not impossible, to identify contemporary questions in biology that are not influenced by microbes. It is also increasingly difficult to assemble an encyclopedia that provides comprehensive coverage of the vast universe of microbes. Despite these challenges, we have engaged the expertise of scientists around the globe to provide an exceptional overview of and perspective on the microbial world. This edition of the *Encyclopedia of Microbiology* will help readers develop a framework for understanding microbes and will provide references directing readers to the primary literature that is needed for a more thorough appreciation of specific topics.

We have included a number of articles which provide a historical perspective of microbiology that is focused on disease—one of humanity's earliest acknowledgment of microbes. These help frame more contemporary issues in microbiology that have moved far beyond the relatively small collection of microbes that cause disease. Rather than simply alphabetize topics as in traditional encyclopedias, articles in the 4th edition are also listed under the following themes in a Subject Classification: Historical, Microbial Diversity, Physiology and Genomics, Ecology and Evolution, Pathogenesis and Immunology, and Technological Advances and Applied Microbiology. We hope this helps readers navigate the work more effectively.

On behalf of an insightful and collegial editorial team, I hope that you emerge from your forays into the *Encyclopedia of Microbiology* with some of the awe that we share for the elegance and power of the microbial world.

Thomas M. Schmidt
Editor-in-Chief

INTRODUCTION: MICROBIAL DIVERSITY

It is what we think we know already that often prevents us from learning.

—Claude Bernard

One of the difficult lessons for any professional scientist is that, as much as we know, as good as our tools and questions are, our knowledge is crude and far smaller than we imagined when we were students. Particularly troublesome is that most fundamental aspects of various scientific fields are simply not very well understood. The physicist wonders what, exactly, “time” is, how space is structured, and why the Planck Constant is $6.62607004 \times 10^{-34} \text{ m}^2 \text{ kg/s}$ instead of any other number you might care to choose. Chemists argue about the nature of a covalent bond, or whether or not transition states exist in reality. Biologists are at a loss to describe how life originated, or even what exactly life (in a general sense) actually is. In the most important book of modern times, “On the Origin of Species,” Charles Darwin clearly (but not concisely) deconstructs the idea of the biological “species,” and despite what many of us learned in school, our view of the “species” even for multicellular sexually reproducing creatures remains murky. The modern reader of “On the Origin of Species” might be forgiven for concluding that the reason for this is that it is the actual *biology* of species, and by extension “life,” our origin, etc., rather than our concepts of them, that are fundamentally disordered.

The subject of this section of the Encyclopedia is Microbial Diversity. What does this mean? What is “microbial diversity?”

Let us start with “microbial.” Literally speaking, the term “microbial” means small living things, usually understood to mean life too small to see with the unaided eye. The scientific field of microbiology, however, mostly emerged from our need to solve crucial health dangers created by a tiny fraction of microbes. As a result, “microbiology,” and so “microbes,” refer to Bacteria (and in modern times the Archaea), fungi, a scattering of problematic single-celled or small multicellular eukaryotes, and the physiological systems of the human body that manages our interactions with these creatures. This sells the microbial world very short. For 85% of the history of our planet, life was *entirely* microbial, and it remains *predominantly* microbial. In the words of Stephen J. Gould, “*We live now in the ‘Age of Bacteria.’ Our planet has always been in the ‘Age of Bacteria,’ ever since the first fossils—bacteria, of course—were entombed in rocks more than 3 billion years ago. On any possible, reasonable or fair criterion, bacteria are—and always have been—the dominant forms of life on Earth.*” Another view of this comes from the phylogenetic perspective. If you scrutinize any objective/quantitative “Tree of Life,” based on molecular sequence analysis or any other criterion of choice, you will quickly discover that nonmicrobial life is limited to the tips of a small number of otherwise un-noteworthy branches. Only from our self-centered anthropocentric viewpoint is microbiology distinguishable from biology as a whole.

And what of “diversity?” Living things and their morphology, structure, physiology, ecology, internal mechanisms, behavior, interactions, etc., are far more diverse than most of us have been led to believe. For example, if you think you know how mitosis works, look it up in *Giardia* and be amazed. The notion of what constitutes a “gene” in the kinetoplast of *Trypanosoma* requires you to throw almost everything you think you know about molecular genetics away. Then have a look through the genome of the archaeon *Nanoarchaeum*. These are just the tips of icebergs; these and many more can be found within the chapters that follow. And yet . . . all of this diversity rests over an almost entirely uniform biochemistry that speaks to the shared ancestry of all living things on Earth. How, then, do we assess the “diversity” of living things? Historically, this meant comparing the morphology of different living things; this was the origin of Linnaean taxonomy and, to be fair, is very useful for organisms on the human size scale. More recently molecular phylogenetics has allowed us to more clearly understand how creatures are related, and draw an objective and quantitative graph of these

relationships; the molecular “Tree of Life” is a more useful roadmap of biological diversity. But it is clear that an even more sophisticated view of biological diversity is required, for example to describe how horizontal gene transfer impacts “diversity,” and many of these questions emerge from microbiology. Perhaps the most important fundamental question in microbiology today is “What is a microbial species?” In other words, how do we conceive of a “species” in organisms that do not reproduce sexually? This is not a trivial or parochial question; remember that the concept of biological evolution, and so the foundation of the science of biology, emerged directly from exploration of what a “species” is and how it originates, in plants and animals. But this was over 150 years ago. Broadening our view of microbial diversity, how it is structured and its history and origins, is the key to new and deeper biological insight.

And so, as is usual in science, attempt to answer a simple question that raises many more questions and provides few answers. What *is* microbial diversity? I dunno, but let us have a look. . . .

James Brown

INTRODUCTION: PHYSIOLOGY AND GENOMICS

The first two editions of EOM were edited entirely by Dr. Joshua Lederberg. The third edition was also planned largely by Dr. Lederberg, but he died during that phase, in 2008, and was replaced by Dr. Moselio Schaechter, promoted from the ranks of associate editors. Dr. Thomas Schmidt was also an associate editor for that edition and moved up to editor-in-chief for the fourth edition.

The time that has passed from the first to the fourth edition has seen remarkable advances in understanding the variety of microbes. Complete genome sequences were determined for 18 microbes by October 1998 and published in the second edition in 2000. By 2019, a single company had determined the complete annotated genome sequences of several thousands of microbes. Comparative genomics, including the ancillary “omics,” as well as the application of systems biology to reconstruct metabolic networks, have provided new insights into many aspects of microbial physiology and genetics. The advent of cryo EM and of single particle cryo EM has revolutionized how we understand the structure of cells and macromolecules. For this fourth edition, we were guided by the splendid organization of the third and additional areas in which considerable advances have been made. The fourth edition now includes articles describing additional features of microbiology: cryo-electron microscopy, CRISPR/*cas*, and metabolic systems biology, as examples of completely new methods to study microbes, circadian rhythms as an important aspect of the physiology of at least one group of microbes, and new developments in our understanding of the many ways in which bacteria and archaea move. We have also made use of updates of chapters that were included in the third edition.

Bianca Brahamsha
Robert Haselkorn

INTRODUCTION: ECOLOGY AND EVOLUTION

Evolution

Seven articles deal with different aspects of evolution. Two articles analyze the remains of the past evolution of microbes in the fossil record. Three other look at theories, mechanisms, and experimental procedures. Two more examine specific aspects of the evolution of viruses and of a ciliate. Finally, one article bridges ecology and evolution looking at the emerging field of evolutionary ecology of microbes.

Ecology

The ecology section contains a few general articles about what microbial ecology is about, and the particularities of the ecology of viruses and rare microorganisms.

The remaining articles can be placed in two complementary approaches: habitat oriented or process oriented. In the first approach there is a lot of attention devoted to extreme environments. These environments are usually exclusively microbial and show the capacity of microbes to deal with really difficult conditions. Besides, the relative simplicity of such ecosystems allows somewhat easier manipulations than in “normal” ecosystems. Several of the latter are also examined in articles ranging from the deep ocean to plastics. Special attention is given to animal and plant habitats and how microbes interact with their hosts.

The process-oriented approach shows, on the one hand, adaptive traits of microorganisms such as the ability to live in diluted environments or to use chemotaxis to find the optimal conditions. One promising and novel avenue to study adaptations is the analysis of the genomes of uncultured microorganisms. On the other hand, several articles review processes relevant at the ecosystem level, from feeding strategies such as myxotrophy to element cycles such as methane formation and oxidation and, finally, to the use of models in microbial ecology.

We hope this collection of articles provides an overview of the exciting times that microbial ecology is going through, with many new discoveries appearing every few years, and a fascinating and invisible world to be explored.

Carlos Pedrós-Alió
Larry Forney

INTRODUCTION: PATHOGENESIS AND IMMUNOLOGY

This section of the encyclopedia focuses on the relatively narrow slice of all microbes that infect living hosts and how the hosts combat these microbes using innate and adaptive immunity. In addition, we examine how antimicrobial agents including unique metabolites and even bacteriophages have been enlisted to combat these infections. This section takes a broad look at infectious agents ranging from prions, viroids, and satellites to the more traditional etiologic agents like bacteria, viruses, fungi, and selected parasites. Also addressed are epidemiologic and diagnostic techniques used to identify and track the spread of infectious microbes including the most advanced diagnostic methods used by the clinical microbiology laboratory. A closer look at pathogenic mechanisms includes groups of virulence factors such as adhesins, iron acquisition, exotoxins of bacteria and fungi, and bacterial endotoxin (lipopolysaccharide). Strategies adopted by bacteria and fungi to colonize implanted foreign bodies such as catheters are also discussed. Plus, infections of the gastrointestinal tract, lung, oral cavity, and the skin are examined. In addition to pathogenic microbes, some articles examine the protective effect of the microbiome and commensal organisms. With respect to immunity this section also focuses on the interplay of the host immune system with pathogenic microbes covering evasion immune strategies in humoral and cellular immunity as well as innate immunology and the complement immune system.

Beth McCormick
Harry Mobley

INTRODUCTION: TECHNOLOGICAL ADVANCES AND APPLIED MICROBIOLOGY

This section focuses on the development and refinement of the tools commonly used for both basic and applied microbiology. The articles in this section are written by authors who personally have worked on developing and fine-tuning technology for research in microbiology. Many of the products and processes described have multiple uses in a variety of disciplines such as health, the environment, food and agriculture, and industrial biocatalysis. The advances made in sequencing, protein analysis, and bioinformatics have given microbiologists new insights into old problems. These advances have also enabled the rapid identification of microorganisms in studies of biowarfare, infectious disease, and pollution of our water sources. At the same time the integration of mathematics and physics with biology and chemistry has provided instrumentation that enables a greater depth of analysis than ever before. Never in the history of microbiology have so many technological advances been developed and commercialized for use by scientists. Microbiologists today are equipped with improved “tools” within the toolbox to push the boundaries of not only elucidating the relationship of microbes to humans, plants and animals but also moving basic research much faster from the bench to development of new products and processes that benefit society and the planet. The renaissance of applied microbiology powered by technological advances has been both exciting and promising in all fields of study.

In memory of Ulysses Lins (1969–2017): Ulysses Lins, a professor at the Microbiology Institute of the Federal University of Rio de Janeiro (UFRJ) Brazil, unexpectedly passed away at age 48. Lins' passion in microbiology was the magnetotactic bacteria, in particular, a unique, uncultured group of these organisms referred to as the "multicellular magnetotactic prokaryotes." The impact of Lins' outstanding work in biomineralization and magnetotactic bacteria cannot be overstated based on numerous important discoveries in his field. For his dedication to microbiology and his sincerity and generosity, his students and colleagues will always remember Professor Ulysses Lins with admiration and respect.

Glossary

Biologically controlled mineralization Highly regulated process in organisms that produces relatively complex materials with specific biological functions and well-organized structures.

Biologically induced mineralization The precipitation and deposition of minerals resulting from secondary chemical interactions between metabolic processes of organisms and the surrounding medium.

Biomineralization The formation of inorganic minerals by biological organisms.

Electron holography Electron interference technique that enables the extraction of amplitude and phase information for an electron wave scattered by a thin electron transparent specimen, in a transmission electron microscope.

Magnetosome Hallmark organelle of magnetotactic bacteria. A magnetosome consists of a nano-sized iron oxide or sulfide magnetic crystal enveloped by a lipid-bilayer membrane containing numerous proteins.

Magnetotactic bacteria Motile bacteria propelled by flagella that are capable of aligning in a magnetic field and navigating along magnetic field lines.

Magnetotaxis The term used to describe the magnetic response observed in magnetotactic bacteria and protists. It consists of the passive orientation and the active motility of the cell along magnetic field lines.

Abbreviations

BCM	Biologically controlled mineralization
BIM	Biologically induced mineralization
MMA	Magnetotactic multicellular aggregates
MMO	Magnetotactic multicellular organisms
MMP	Many-celled magnetotactic prokaryotes
PCR	Polymerase chain reaction

Introduction

Many bacteria are motile and swim using flagella and as they do, their swimming pattern changes from being random to being directed toward a more favorable environment. This more favorable environment, which varies from species to species, is tracked on

[☆]*Change History:* May 2018. D Acosta-Avalos, Pedro Leão, Fernanda Abreu and Dennis A Bazylinski updated the text and further readings to this entire article. This article is an update of U. Lins, D.A. Bazylinski, Magnetotaxis, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 229–241.

the basis of sensing changes in a range of stimuli that includes both chemicals like nutrients and toxins and physical parameters like pH, light, and temperature. This behavioral response to directional stimuli is called taxis; more specifically, if the organism swims toward the stimulus, it is called positive taxis; and if away from the stimulus, it is called negative taxis. Among the most-studied stimuli and tactic responses in bacteria are: chemicals and chemotaxis; and light and phototaxis. This article deals with an unusual bacterial behavior in magnetic fields called magnetotaxis. It should be pointed out, however, that magnetotaxis is very different than other types of taxis in that magnetotactic bacteria do not swim toward or away from a magnetic field and only passively align along magnetic field lines like a compass needle.

The geomagnetic field is considered to be one of several important environmental cues for navigation by many different biological organisms. The Earth's geomagnetic field is important for life on this planet for several reasons including the fact that it creates a planetary shield against the solar wind and that it appears to be responsible for the orientation and migration by a relative large number of biological species. Different organisms that have been shown to respond in some way to the Earth's geomagnetic field include homing pigeons and other migratory birds, trout, sea turtles, social insects such as honeybees and ants, and the worm *Caenorhabditis elegans*. Among the microbes, the motility of several types of bacteria and protists is affected by magnetic fields. This behavior is referred to as magnetotaxis and the organisms as being magnetotactic. Magnetotactic microbes represent the best-understood example of magnetically influenced, biological navigation on Earth.

The first report of magnetotactic bacteria was made by Salvatore Bellini in 1963 in a publication of the Microbiology Institute (Istituto di Microbiologia) of the University of Pavia, Italy. His microscopic observations of freshwater sediments revealed large numbers of bacteria that swam in a single, consistent direction. Bellini realized that the bacteria swam toward the North Pole and hence called them magnetosensitive bacteria (batteri magnetosensibili). He presumed that some sort of biomagnetic compass was present in the bacteria. His idea proved to be true. Richard P. Blakemore, then a Microbiology graduate student at the University of Massachusetts at Amherst, reported in the journal *Science* in 1975, similar magnetosensitive behavior of bacteria in sediments collected from a freshwater swamp in Woods Hole, Massachusetts. He discovered that these magnetosensitive bacteria contained electron-dense, iron-rich crystalline inclusions. Blakemore also realized that these microorganisms were swimming toward the geomagnetic north in the Earth's magnetic field and named them magnetotactic bacteria and their behavior magnetotaxis. Since then, many multidisciplinary studies have been done on these microorganisms, many of which include recent advances toward understanding the molecular mechanisms underlying the biomineralization and ultrastructural organization of magnetosomes in bacteria. The controlled synthesis and organization of lipid-bilayer membrane-bounded organelles, the magnetosomes, using specific cytoskeleton elements has caused rethinking on some of the traditional boundaries used to distinguish eukaryotic cells from their prokaryotic counterparts, as prokaryotes were thought to not contain lipid-bilayer membrane-bounded organelles or an organized cytoskeleton. Magnetotactic bacteria are increasingly becoming the cell biology model for understanding the molecular mechanisms underlying the basic rules that govern the intracellular ultrastructural organization of prokaryotes.

Despite the efforts of a number of different research groups since 1980, relatively few representatives of magnetotactic bacteria have been isolated and cultivated in axenic culture. Due to a number of important improvements in developing growth media for these organisms, approximately 25 pure cultures of magnetotactic bacterial species have been isolated although only a subset of these have been validly named or available in microbial repositories for study. Difficulties in culturing members of this group are related to their fastidiousness as to specific growth requirements and their overall diversity among species. As a consequence, relatively little is known regarding their metabolic/physiological characteristics and versatility; many studies on their diverse morphology and phylogeny as well as mineralogy of their magnetosomes have relied on culture-independent methods.

General Features of Magnetotactic Bacteria

The term "magnetotactic bacteria" has no taxonomic significance and represents a heterogeneous group of bacteria with various cell morphologies/phylogenies/physiologies. The operational definition of magnetotactic bacteria is that they are a heterogeneous collection of prokaryotes that share the traits of magnetotaxis and the biomineralization of magnetosomes. The magnetosome is defined as an intracellular organelle consisting of a single-magnetic-domain crystal of a magnetic iron mineral enveloped by a lipid-bilayer membrane that contains proteins that are unique to it. Despite their heterogeneity, there are other features shared by these microorganisms.

Magnetotactic bacteria are morphologically diverse, comprising cocci, rods, spirilla, vibrios, and multicellular forms. All possess a Gram-negative cell wall and are phylogenetically associated with Gram-negative groups of prokaryotes (the *Proteobacteria* and the *Nitrospirae* phyla; the candidate phylum "Omnitrophica" of the *Planctomycetes-Verrucomicrobia-Chlamydiae* (PVC) superphylum and, possibly the candidate phylum "Latescibacteria") in the domain *Bacteria*. Although magnetotactic bacteria appear to be restricted to the domain *Bacteria*, there are no known specific reasons why there are no magnetotactic representatives phylogenetically associated with the *Archaea* and *Eukarya* domains. Eukaryotic microbes (protists) that respond to an applied magnetic field similarly to magnetotactic bacteria have been reported. However, this behavior appears to be associated with the ingestion of magnetotactic bacteria by these protists, leading to a temporary response to magnetic fields. Until now, there is no evidence to fully support autonomous magnetosome biomineralization in eukaryotes.

All currently known magnetotactic bacteria are motile by means of flagella. Because most studies on uncultivated magnetotactic bacteria relied on the use of a magnetic field for retrieving cells from water and sediment samples, it is possible that nonmotile bacteria that synthesize magnetosomes exist that would not swim toward the magnet and thus would not be collected and observed.

By definition, the latter organisms would be magnetic rather than magnetotactic (the term tactic here implies motility). Flagellation patterns in magnetotactic bacteria vary greatly and include polarly monotrichous, bipolar, or lophotrichous (possessing two tufts or bundles of flagella) representatives. The number of flagella per cell ranges from one in the marine vibrio, *Magnetovibrio blakemorei* strain MV-1, to over a thousand in the many-celled magnetotactic prokaryotes (MMPs). The swimming velocity also varies greatly between species and ranges from about 40 μm per second in members of the genus *Magnetospirillum* to over 1000 μm per second in some of the magnetotactic cocci. Although motility is a key factor in magnetotaxis, little is known about the structural and molecular components of flagella in magnetotactic bacteria. In some cases, the flagella in many magnetotactic bacteria (e.g., the magnetococci) are shorter than those of many other bacteria (e.g., *Escherichia coli*) (Fig. 1). Tufts or bundles of flagella are typical of the magnetotactic cocci and originate from a disk-shaped depression or pit on the cell. Targeted disruption of the flagellin gene *flaA* was found to eliminate flagella formation and motility in *Magnetospirillum gryphiswaldense*. Large numbers of flagella are distributed only on one side of each of the cells of the MMP; the part of the cell exposed to the environment and thus the entire organism can be considered to be peritrichously flagellated.

Recently several studies with the magnetotactic coccus *Candidatus Magnetococcus massalia*, strain MO-1, isolated from the Mediterranean Sea and capable of swimming 300 μm per second, revealed some interesting features of the flagella properties of the magnetotactic cocci. In this strain, the flagella are powered by proton-motive force and a sodium ion gradient. The flagellar bundle is enclosed by a sheath described as a six-part, right-handed helical tubular structure with a diameter of about 100 nm and a helical pitch of about 260 nm. This sheath consists of a glycoprotein called a “sheath-associated protein” (Sap) and shows some conserved amino acid sequence with some known bacterial adhesins and eukaryotic cadherin. Every bundle contains seven flagella, with six individual flagella organized as a hexagon and the seventh in the middle. Strain MO-1 contains 14 homologs of flagellin genes encoded in the genome. In general, the genomes of magnetotactic bacteria contain more flagella-associated genes than the genomes of nonmagnetotactic bacteria. This characteristic might be associated with special swimming patterns or even the very high swimming velocities observed in the magnetotactic cocci.

Most magnetotactic bacteria swim in helical tracks. The flagella force the cell body of the bacterium to rotate around its axis while the cell is propelled by the flagella. Under the influence of the geomagnetic field, the consequence of the action of the short flagella is a misalignment of the trajectories that enables the cells to change the trajectory direction when they, for example, hit an obstacle in the sediment. The small misalignments during movement might be essential for certain magnetotactic bacteria to escape from physical “traps” present in sediments where they thrive. Recently, high-speed imaging showed that the trajectory of a magnetococcus was linear rather than helical as previously reported.

Magnetotactic bacteria are distributed worldwide in aquatic habitats that are neutral or close to neutral in pH. In general, they inhabit many aquatic environments where there is strong chemical stratification, that is, where vertical chemical (e.g., O_2) concentration gradients exist. In general, magnetotactic bacteria are obligately microaerophilic and/or anaerobic organisms and display a negative tactic and/or growth response to high concentrations of O_2 but also show a positive aerotactic response to low concentrations of O_2 (these two responses are generally referred to as aerotaxis). In natural environments they appear to prefer to be located at the oxic–anoxic interface where they are found in their highest numbers. This interface can occur in the water column or in the uppermost millimeters to centimeters of unconsolidated sediments depending on the environment.

In general, most magnetotactic bacteria biomineralize a single type of mineral in their magnetosomes: either the iron oxide magnetite (Fe_3O_4) or one or more iron sulfide, for example, greigite (Fe_3S_4) and its chemical precursors. The shape of the

Fig. 1 Transmission electron micrograph of a freshwater magnetotactic bacterium. Three rows or chains (arrows) of bullet-shaped magnetosomes can be seen aligned parallel to the main axis of the cell. A flagella bundle is present at one end of the cell (white arrow). Several intracellular (internal) granules, possibly sulfur-rich inclusions, are also present (arrowheads).

magnetosome crystals is also considered to be species-specific. Currently described magnetosome crystal shapes include cuboctahedral (roughly cubic), elongated prismatic (appear rectangular in projection), bullet- or tooth-shaped, and pleomorphic (irregularly shaped more typical for greigite magnetosomes). Magnetite producers are usually found at the oxic–anoxic interface proper or slightly above it while some magnetotactic bacteria, particularly those that produce the iron sulfide greigite, are generally found below the oxic–anoxic interface in the anaerobic zone where sulfide is also present. It was thought that all freshwater magnetotactic bacteria and some marine, estuarine, and salt marsh morphotypes produce magnetite. However, greigite-producing magnetotactic bacteria, only previously found in brackish to marine environments, have been recently reported in freshwater environments. Many magnetotactic rod-shaped magnetotactic bacteria biomineralize both magnetite and greigite magnetosomes (sometimes in the same chain) and have also been reported from freshwater environments. The recently formally named *Desulfamplus magnetovallimortis* strain BW-1, isolated from a brackish spring at Badwater Basin, Death Valley National Park, California (United States) is an excellent cultured example of a magnetotactic bacterium that biomineralizes both minerals.

All magnetotactic strains in pure culture produce magnetite magnetosomes except *Desulfamplus magnetovallimortis* strain BW-1 which biomineralizes both mineral types in culture depending on conditions. Metabolically, all cultivated strains of magnetotactic bacteria have a respiratory metabolism and are unable to ferment except for *Desulfovibrio magneticus* strain RS-1 which has a solely chemoorganoheterotrophic metabolism and ferments pyruvate to acetate, CO₂, and H₂ in the absence of a terminal electron acceptor. Most known magnetotactic bacteria are mesophilic with respect to growth temperatures. Only recently have extremophilic MTB been described, including alkaliphilic, psychrophilic, halophilic and moderate thermophilic species. *Candidatus Thermomagnetovibrio paiutensis* strain HSMV-1 is an uncultured, moderately thermophilic magnetotactic bacterium found in Great Boiling Springs located in Nevada, United States, at temperatures close to 63°C but not higher. Three different magnetotactic strains were isolated from highly alkaline environments in California, United States. These alkaliphilic strains, designated as ML-1, ZZ-1 and AV-1, show optimal growth at pH values between 9.0 and 9.5. Psychrophilic magnetotactic bacteria, predominantly cocci, have been described in sediments from the Antarctic maritime region. The sequenced genomes of most cultivated magnetotactic bacteria contain the *nif* genes responsible for the fixation of atmospheric N₂ and almost all strains that have been tested exhibit nitrogenase activity. Because N₂ fixation is an O₂-sensitive process, microaerophilic magnetotactic bacteria might be further restricted to the oxic–anoxic interface in nitrogen-limited environments.

Characterization of Magnetotactic Bacteria in Pure Culture

All cultured magnetotactic bacteria phylogenetically belong to the *Proteobacteria* phylum (Table 1), most affiliated with the *Alphaproteobacteria* class. *Magnetospirillum* species make up most of the currently cultured magnetotactic bacteria and are freshwater, facultatively anaerobic microaerophiles that show varying tolerances to O₂ and biomineralize cuboctahedral crystals of magnetite in their magnetosomes. They are chemoorganoheterotrophs that use organic acids (e.g., succinic) as a source of electrons and carbon but several have the potential for chemolithoautotrophy as at least one strain has been shown to grow autotrophically and as many strains possess the gene for ribulose-1,5-bisphosphate carboxylase/oxygenase, a key enzyme of the Calvin-Benson-Bassham cycle for autotrophy, in their genomes. In addition to oxygen, most strains can use nitrate as an alternate terminal electron acceptor for

Gammaproteobacteria	Strain BW-2	Rod	Magnetite	Cuboctahedral

anaerobic growth. Thus far, there are seven validly described species of *Magnetospirillum*: *M. magnetotacticum* strain MS-1, *M. gryphiswaldense* strain MSR-1, *M. magneticum* strain AMB-1, *M. caucaseum* strain SO-1, *M. marisnigri* strain SP-1, *M. moscoviense* strain BB-1, and *M. bellicus* strain VDY. Of these seven strains, cells of *M. bellicus* are unusual in that they are apparently unable to biomineralize magnetosomes. A number of other strains of this genus have also been cultivated and partially characterized but not validly named. Interestingly, several related nonmagnetotactic spirilla with ~95% 16S rDNA sequence similarity to known species of *Magnetospirillum* have also been isolated. Tractable genetic systems have been developed for *M. gryphiswaldense* and *M. magneticum*.

Cultured marine species belonging to the *Alphaproteobacteria* include: the marine vibrio *Magnetovibrio blakemorei* strain MV-1; two species of cocci, *Magnetococcus marinus* strain MC-1 and *Magnetofaba australis* strain IT-1; and the spirillum *Magnetospira thiophila* strain MMS-1 and *Magnetospira* sp. strain QH-2. All of these strains are facultative chemolithoautotrophs also being able to grow chemoorganoheterotrophically. *Magnetovibrio blakemorei* strain MV-1 and *Magnetospira thiophila* strain MMS-1 utilize the Calvin-Benson-Bassham cycle for autotrophy, while *Magnetococcus marinus* strain MC-1 and *Magnetofaba australis* strain IT-1 utilize the reverse or reductive tricarboxylic acid cycle for autotrophy. All four strains oxidize reduced sulfur compounds (e.g., sulfide and/or thiosulfate) as a source of electrons and produce intracellular sulfur-rich globules. In marine, chemically stratified environments where an oxygen: sulfide double inverse concentration gradient exists, oxygen and sulfide generally overlap at the oxic–anoxic interface. Because these marine species require both compounds for energy, these organisms are restricted to the oxic–anoxic interface. Interestingly, many uncultivated cells of magnetite-producing magnetotactic bacteria collected from these environments also contain intracellular sulfur-rich globules suggesting that they also oxidize reduced sulfur compounds as a source of electrons. Strain MV-1 is a facultatively anaerobic microaerophile, capable of anaerobic respiration on some nitrogen oxides (e.g., nitrate, nitrous oxide) while strains MC-1, IT-1 and MMS-1 appear to be obligate microaerophiles. All four species biomineralize elongated prismatic crystals of magnetite in their magnetosomes.

A few magnetotactic bacterial strains from proteobacterial classes other than the *Alphaproteobacteria* have also been isolated in axenic culture. These include strains from the *Gamma*- and *Deltaproteobacteria*. *Gamma*proteobacterial strains include BW-2 and SS-5. Both are rod-shaped and are chemolithoautotrophs that oxidize reduced sulfur compounds for electrons and use the Calvin-Benson-Bassham cycle for autotrophy. Cells of strain BW-2 and SS-5 biomineralize cuboctahedral and elongated prismatic crystals of magnetite, respectively. Cultivated magnetotactic strains from the *Deltaproteobacteria* are all chemoorganoheterotrophic and dissimilatory sulfate reducing bacteria and include: *Desulfovibrio magneticus* strain RS-1 a curved rod-shaped sulfate-reducing bacterium that can also reduce fumarate as a terminal electron acceptor and has recently been shown to grow microaerobically; *Desulfamplus magnetovallimortis* strain BW-1, an obligately anaerobic bacterium; and several strains of obligately anaerobic, alkali-philic bacteria isolated from strongly alkaline habitats all very closely related to the bacterium *Desulfonatronum thiodismutans*. All *deltaproteobacterial* magnetotactic bacteria biomineralize bullet-shaped magnetite crystals with the exception of *D. magnetovallimortis* strain BW-1 which biomineralizes greigite as well as bullet-shaped magnetites.

Characterization of Uncultured Magnetotactic Bacteria

The presence of magnetosomes and the trait of magnetotaxis allow for the magnetic manipulation and easy retrieval of uncultured magnetotactic bacteria from environmental samples with the aid of a magnetic field. Our current knowledge regarding the diversity of magnetotactic bacteria is based more on microorganisms harvested from the environment than on the isolation and characterization of pure cultures. Thanks to modern molecular techniques including the polymerase chain reaction (PCR), it is relatively easy to obtain and analyze the sequence of their 16S rRNA genes and therefore be able to determine phylogenetic relationships of these organisms.

The most commonly found morphotype of magnetotactic bacteria found in marine and freshwater environments are the magnetococci and thus numerous culture-independent studies have been focused on these organisms (Table 2). In addition, the magnetotactic cocci, unlike many other magnetotactic morphotypes, persist for long periods in microcosm experiments. All known magnetotactic cocci are phylogenetically affiliated with the *Alphaproteobacteria* class of the *Proteobacteria* phylum but are not closely related to any other *alphaproteobacterium* and appear to form a unique lineage within the group. All magnetotactic cocci biomineralize elongated prismatic crystals of magnetite although the arrangement of the crystals is variable including those with multiple chains and those with a clump (rather than a chain) of magnetosomes at one side of the cell (Fig. 2).

The techniques of gold labeling in conjunction with in situ hybridization and transmission electron microscopy revealed the presence of at least three different types of uncultured magnetococci in the Itaipu Lagoon in Brazil (Fig. 3). In this case, polyribonucleotide probes were labeled with digoxigenin or fluorescein and detected by immunolabeling with antifluorescein and antidigoxigenin antibodies bound to 10 and 15 nm gold particles. The use of this technique allowed for the correlation of phylogenetic association with a specific magnetosome morphology and organization; that is, to determine which 16S rRNA gene sequence belonged to which of the three cocci. The cocci were distributed as two clusters, referred to as Itaipu-1 and Itaipu-2, and were closely related based on 16S rRNA gene sequences which also showed they belonged to the *Alphaproteobacteria*.

A number of as yet uncultured magnetotactic bacteria are phylogenetically affiliated with the *Nitrospirae* phylum. Morphotypes of MTB phylogenetically associated with this phylum include: large rod- and ovoid-shaped cells and vibrios (Table 2).

Large numbers of a barbell-shaped magnetotactic bacterium were discovered in a chemically stratified coastal salt pond that displayed unusual magnetotactic behavior (discussed in the *Magneto-aerotaxis* section). This microorganism appears to consist of a

chain of two to five cocci and belongs phylogenetically to the *Deltaproteobacteria*. Unfortunately, the composition of the magnetosome mineral was not determined.

An uncultured, relatively large (~5 μm long) slow-moving rod was retrieved from the chemically stratified Salt Pond, Woods Hole, United States and was found to be a member of the *Gammaproteobacteria* class of the *Proteobacteria* although there is some doubt as to the phylogenetic affiliation of this organism (Table 2).

Although one magnetotactic bacterium capable of producing both magnetite- and greigite-containing magnetosomes has been isolated in pure culture (discussed in the previous section), a number of uncultured magnetotactic bacteria have been described that are capable of biomineralizing both minerals and partially characterized using culture-independent techniques, including genomics. Evidence for the common ancestry of magnetite and greigite biomineralization in magnetotactic bacteria was revealed through the partial sequencing of the genome of an uncultured greigite-producing multicellular magnetotactic bacterium from sulfide-rich environment after magnetic concentration and separation. This approach allowed for the identification of specific genes considered unique for magnetite magnetosome synthesis.

Fig. 3 Transmission electron microscope image of an ultra-thin section of a cell of a magnetic coccus collected from the Itaipu Lagoon in Brazil classified as *Itaipu-1*. Section was hybridized with a 16S rRNA gene-digoxigenin probe and detected by antidigoxigenin antibodies conjugated with 10 nm gold particles (arrows). Magnetosomes can be seen (arrowhead).

Fig. 4 Transmission electron microscopy image of a cell of a multicellular magnetotactic bacterium containing chains of bullet-shaped magnetite (arrowheads) and rounded greigite magnetosomes (arrows).

Morphologically conspicuous, multicellular magnetotactic bacteria have been reported from a number of different brackish, marine, or hypersaline environments in both the Northern and the Southern Hemispheres, usually in sulfide-rich environments very likely to be anaerobic (Table 2). These very unusual organisms are assemblage of Gram-negative cells that generally contain chains of greigite-containing magnetosomes. These organisms are not a consortium of cells of different species, but an aggregate of genetically identical cells. All those examined are phylogenetically affiliated with the *Deltaproteobacteria* class of the *Proteobacteria* phylum (Table 2). For many years, because of their unique morphology, these multicellular bacteria were thought to represent a single species. However, phylogenetic analyses of a collection of these organisms from a natural population present in a salt marsh (Falmouth, MA, United States) showed that this group of multicellular prokaryotes had a number of different 16S rRNA gene sequences separated by at least 5% divergence, suggesting that they are not a single species but represent a number of distinct species within a single genus. An unaffiliated multicellular magnetotactic bacterium capable of producing both greigite and magnetite magnetosomes was also reported (Fig. 4). Although several ellipsoidal-shaped types containing both magnetite and greigite have been characterized (Fig. 5), most multicellular magnetotactic bacteria are spherical in shape (Fig. 6).

These organisms have not yet been validly named (largely because they have not been isolated and grown in pure culture) and confusing and imprecise terminology has been used for them including magnetotactic multicellular aggregates (MMAs), many-celled magnetotactic prokaryotes (MMPs), and magnetotactic multicellular organisms (MMOs).

Fig. 5 Electron microscopy of ellipsoidal MMPs. (A) Scanning electron microscopy image of the microorganism showing cells organized as an ovoid-shape structure. Fig. 6 Scanning electron microscopy image of *Candidatus Magnetoglobus multicellularis* showing its multicellular nature and its overall spherical morphology.

Like other spherical multicellular magnetotactic prokaryotes, *Candidatus Magnetoglobus multicellularis* is a member of the *Deltaproteobacteria* (Table 2). The most conspicuous structural feature of these microorganisms is the fact that its cells appear to be precisely organized and must live as a “colony” or unit and are unable to live individually (Fig. 7). Each cell faces both the external surrounding environment and the internal portion of the aggregate. If a cell leaves the assemblage, for example, when the organism dies, it loses its ability to swim and to orientate along magnetic field lines.

Candidatus Magnetoglobus multicellularis exhibits a unique method of reproduction. This has been studied in some detail and the following growth stages have been proposed: (1) individual cells grow in size thereby increasing their volume and their number of magnetosomes; (2) the cells then divide doubling the number of cells in the microorganism; (3) individual cell within the microorganism then reorganize; and (4) the microorganism divides into two new and identical units.

On the outer surface of the microorganism, cells of multicellular magnetotactic prokaryotes are covered with numerous flagella that are responsible for its coordinated complex movement. Four different types of motility have been observed in *Candidatus*

Fig. 7 Transmission electron microscopy image of an ultra-thin section of *Candidatus Magnetoglobus multicellularis* showing the general organization of cells and the internal compartment (at *asterisk*). All cells have a cell wall surface structure of Gram-negative bacteria and face both the external environment and the internal compartment. The numerous magnetosomes occur mostly at the periphery of the cells (arrows). Lipid or polyhydroxyalkanoate inclusions are marked (L).

Table 3 Motility of multicellular magnetotactic prokaryotes

Motility	Description
Free motion	The microorganism swims at speed up to $100 \mu\text{m s}^{-1}$ in either straight or helical trajectories along magnetic field lines in a uniform magnetic field
Rotation	At the edge of a drop under atmospheric conditions, the microorganism spins around an axis that passes through its center
Walking	At the air–water interface on the top of the drop, the microorganism swims freely in a complex trajectory, maintaining the same sense of body rotation
Escape	This movement consists of a backward movement (north-seeking in the Southern Hemisphere or south-seeking in the Northern Hemisphere) for tens or even hundreds of micrometers, followed by a forward regular movement. In the backward movement, the microorganisms decelerate continuously with time, whereas in the forward movement that follows, they display uniform acceleration. Also known as “ping-pong” response

Magnetoglobus multicellularis: free motion, rotation, walking, and escape motilities (Table 3). Coordination among cells in the multicellular prokaryote are considered necessary for all types of motility. A negative photo response has been observed in a multicellular magnetotactic prokaryote when illuminated with high intensity UV light (365 nm), violet-blue light (395–440 nm filter) of about 80 W m^{-2} of intensity and blue light (450–490 nm filter) of about 200 W m^{-2} of intensity. For longer wavelengths no photo response was observed. Photo kinesis has been observed in this multicellular magnetotactic prokaryote, decreasing their velocity when illuminated with green light (517 nm, 0.46 W m^{-2}) and increasing their velocity when illuminated with red light (628 nm, 0.16 W m^{-2}), both respectively to the velocity observed when illuminated with blue light (469 nm, 0.8 W m^{-2}). That effect is related to the presence of a constant magnetic field and it can be canceled in the presence of radio-frequency electromagnetic field at the Zeeman resonance frequency, showing the involvement of a radical pair mechanism, a very well-known magnetoreception mechanism used by migratory birds.

Unusual ellipsoidal-shaped multicellular magnetotactic prokaryotes were discovered in sediments and water from the intertidal zone of the Yellow Sea in Qingdao (Tsingtao) City, China and were present along with spherical types (Table 2). Magnetosomes were organized in chains close to parallel to the long axis of the organism. Motility in the ellipsoidal multicellular magnetotactic prokaryotes was similar to that of spherical types, showing the characteristic “escape” motility and also negative phototaxis for UV, violet and blue light.

Spherical multicellular magnetotactic prokaryotes change their behavior with magnetic field intensity in a way that cannot be explained by the simple compass model used for magnetotaxis in unicellular bacteria. This unexpected behavior led to the hypothesis that multicellular magnetotactic prokaryotes have a sort of magnetoreception mechanism in magnetic fields higher in intensity than that of the Earth’s geomagnetic field. This magnetoreception mechanism and the unusual “escape” motility might imply transference of information from the magnetic interaction of the magnetosome chains to the flagellar motors. There is, however, no scientific evidence for any type of magnetic “sensor” such as this in magnetotactic bacteria.

Magnetosomes

Many prokaryotic microorganisms facilitate the formation of a large number of various minerals, including magnetosome crystals, through one of two biomineralization processes. These include biologically induced mineralization (BIM) and biologically controlled mineralization (BCM). There are several important differences between BIM and BCM. The most important differences relate to the control of the synthesis of the biominerals and the functionality of the biomineralized products. Generally, in BIM the microorganism exerts little control over the biomineral, which has no known recognized function for the bacterium. In BCM, the microorganism exerts strict crystallochemical control over the nucleation and growth of the biomineral, which in some cases has a somewhat defined function. Because of these features, BCM processes are considered to be under specific biochemical and genetic control. Examples of products of BCM in higher organisms are bones, teeth, or shells. In the microbial world, most known biominerals are produced by bacteria through BIM. The mineral particles produced by bacteria in BCM are characterized as well-ordered crystals with narrow size distributions, high chemical purity, and specific particle morphologies (Fig. 8). Generally, biomineralized particles produce through BIM lack these qualities. The most characterized example of BCM in bacteria is the magnetosome.

Magnetosomes are iron oxide or sulfide magnetic crystals, each enveloped by a lipid bilayer membrane (i.e., the magnetosome membrane). As previously stated, there are two compositional types of magnetic minerals in magnetosomes: magnetite (Fe_3O_4) and greigite (Fe_3S_4). Additional nonmagnetic iron sulfide minerals, including mackinawite (tetragonal FeS) and a cubic form of FeS , have been found in some greigite-producing magnetotactic bacteria and are assumed to represent precursors of greigite. In most

Fig. 8 Transmission electron microscopy images of magnetosome magnetite crystal morphologies. (A) Cell of *Magnetospirillum magnetotacticum* containing a chain of cuboctahedral magnetosomes (arrow), (B) an uncultivated marine coccus with two chains of elongated prismatic magnetosomes (arrows), (C) uncultured freshwater magnetotactic bacterium with rows of bullet-shaped magnetosomes (arrows) and sulfur-rich inclusion (arrowheads).

Fig. 9 High-resolution transmission electron microscopy image of a bullet-shaped magnetite magnetosome biomineralized by magnetotactic bacteria.

magnetotactic bacteria, magnetosomes are organized in a chain or chains within the cell. This has important physical significance and is discussed later.

The nature of the magnetosome membrane has been studied in several magnetite-producing *Magnetospirillum* species. The magnetosome membrane appears to originate as an invagination of the cell membrane and contains a number of proteins unique to it that are thought to be responsible for regulating the size, the chemical purity, and the morphology of the magnetosome crystal.

The crystalline phase of the magnetosome has been extensively studied using a number of forms of electron microscopy. Magnetotactic bacterial magnetite typically has cubic {100}, octahedral {111}, and dodecahedral {110} faces in crystals that have quasi-rectangular projected shapes in the horizontal plane or are bullet-, tooth-, or arrowhead-shaped (Fig. 9). Morphologies of greigite crystals are similar and include the same forms as magnetite but, in contrast, the crystals often appear “wrinkled” and have an irregular border. The number of magnetosomes varies from a few to thousands per cell.

Regardless of mineral type, magnetosome crystals are generally in the size range of 35–120 nm, which corresponds to the single-magnetic-domain size range for magnetite or greigite. However, magnetosomes up to 250 nm have been reported. The significance of the size of the mineral crystals is discussed in the next section.

Biophysics of Magnetotaxis

As previously stated, in general, the sizes of magnetosome crystals in magnetotactic bacteria are within the permanent single-magnetic-domain size range for magnetite (~35–120 nm), meaning that they are uniformly magnetized with the maximum magnetic dipole moment per unit volume. Magnetosomes larger than single magnetic domains are not uniformly magnetized because of the formation of domain walls, resulting in multiple magnetic domains. The overall effect of being larger than the single-magnetic-domain size range is the significant reduction of the magnetic dipole moment. On the other hand, very small particles (<35 nm) are superparamagnetic, which means that they are still uniformly magnetized but their magnetic dipole moments are not constant because of thermally induced spontaneous reversals. This results in a net magnetic moment of zero over time. Thus, the single-domain size range is the optimum particle size for the maximum magnetic dipole moment in a magnetosome.

Magnetosomes are anchored to the cell membrane in most, if not all, magnetotactic bacteria and are thus fixed in place within the cell. In most magnetotactic bacteria, the magnetosomes are arranged as a chain or multiple chains. Experimental evidence

involving *Magnetospirillum* species shows that magnetic interactions between the crystals are not sufficient to align them in a chain. The initial step in the biomineralization process is the invagination of the cytoplasmic membrane to form the magnetosome membrane vesicle. Magnetite or greigite are biomineralized within these vesicles and may possibly nucleate even while the magnetosome membrane is still an invagination with a connection to the periplasm. In most magnetotactic bacteria, at some point, it is thought that the membrane invagination detaches from the cytoplasmic membrane, forming a separate magnetosome vesicle. However, in cells of *Magnetospirillum magneticum* strain AMB-1, the magnetosome membrane may remain as cell membrane invaginations. In both cases, cytoskeletal filaments composed by the protein MamK, an actin-like MreB homologue, are necessary to organize the magnetosomes in chain in the cytoplasm and attach this structure to the cellular framework. This results in an efficient transfer of torque to the cell body when the cell is in a magnetic field.

A number of the genes thought to be involved in the formation of the magnetosome membrane and biomineralization of magnetite/greigite have been studied. Several different genes have been identified that encode magnetosome-associated proteins using cultured *Magnetospirillum* species as a model (mainly *Magnetospirillum gryphiswaldense* strain MSR-1). Most genes associated thought to be involved with magnetosome biogenesis are unique to magnetotactic bacteria. In *Magnetospirillum gryphiswaldense* these genes are clustered in a region of the genome that is flanked and interrupted by transposase and tRNA genes. These are features typical of what is referred to as a genomic island and thus, this genomic region in *Magnetospirillum gryphiswaldense* is referred to as a magnetosome island (MAI). In the magnetotactic *Alphaproteobacteria*, set of approximately 30 genes have been described and named the *mam* (magnetosome membrane) and *mms* (magnetic particle membrane specific) genes. The following steps have been described for the BCM biomineralization process of magnetosomes based on studies using *Magnetospirillum* species: (1) invagination of the cytoplasmic membrane to form the magnetosome vesicle; (2) iron transport into the vesicle by the action of the cation transporters MamM and MamB; (3) nucleation and controlled growth of the magnetic crystals; (4) formation of magnetosome chains through the interaction of MamJ on the magnetosome vesicle with the cytoskeletal filament protein MamK and positioning the magnetosome chain in the middle of the cell.

The magnetosome chain(s) within the cell impart a magnetic dipole moment to the cell that overcomes the thermal forces that tend to randomize the position of the cell in the aqueous environment in which the bacteria live. The magnetosome chain causes the cell to behave as a miniature magnetic compass needle, continuously causing the cell to passively align along local magnetic field lines. This alignment is not perfect however and disturbed mostly by the thermal fluctuations of the aqueous medium. Thus the alignment of magnetotactic bacteria along geomagnetic field lines depends on the ratio the magnetic to thermal energies, or $MB/k_B T$, where M is the magnetic dipole moment of the cell, B is the geomagnetic field strength, k_B is the Boltzmann constant, and T is the ambient temperature. When magnetosomes are arranged in a linear chain within the bacterial cell, the total magnetic dipole moment of the cell is the sum of the magnetic dipole moments of the individual crystals. The organization of magnetosomes in chains causes the individual magnetic dipole moments of the single-magnetic-domain magnetosome crystals to orient parallel to each other along the chain. In this case, the permanent magnetic dipole moment for the entire chain is optimum, that is, it approaches the maximum value possible. Electron holography in the electron microscope, magnetic force microscopy and pulsed-magnetic-field remanence measurements on individual cells have demonstrated the permanent magnetic microstructure of the magnetosome chain(s).

At ambient temperature, 10–20 magnetosomes (~50 nm in diameter) in a chain would be sufficient for passive orientation of a magnetotactic bacterium along the Earth's magnetic field lines. The efficient orientation in the geomagnetic field results in the migration of the cell along the magnetic field lines as it swims. If the magnetic field is increased (e.g., by exposing the cells to a bar magnet), the time-averaged orientation of the cell along the field is increased and the migration rate of the cell in the magnetic field direction is increased, even though the swimming speed of the cell remains unchanged.

Intriguingly, many magnetotactic bacteria seem to produce more magnetosomes than is necessary for orientation suggesting that magnetosomes might be responsible for other roles, perhaps physiological, than simply the magnetic orientation of the cell. Unusually large magnetite-containing magnetosomes (up to ~250 nm in length) were reported in an uncultured magnetotactic coccus, named Itaipu-1, collected from the Itaipu Lagoon, near Rio de Janeiro, Brazil. Because of the large size of the magnetic crystals, they would be expected to be outside the single-magnetic-domain range. However, electron holography measurements demonstrated that the crystals in fact behave as single-magnetic-domains while they are organized in chains. Breaking or removal of these magnetosome crystals from the chains results in a complicated magnetic microstructure with domain walls.

The functional significance of the unusually large volume of the magnetosomes is unknown. It has been speculated that the large crystals in Itaipu-1 occur in order to compensate for the anomalous low magnetic field strength (0.23 gauss) of the South Atlantic Magnetic Anomaly region, which includes Itaipu Lagoon. However, a calculation of the total magnetic dipole moment for a typical Itaipu-1 cell results in $MB/k_B T = \sim 250$, which is over 10 times the minimum value required for efficient magnetotaxis, suggesting there may be other functions of the magnetosomes in Itaipu-1.

Magnetotaxis

It is important to understand that magnetotaxis is somewhat of a misnomer and does not represent a true taxis response as in phototaxis or chemotaxis. Magnetotactic cells do not swim toward or away from a magnetic field source. Instead, magnetotaxis is the combination of the passive orientation and active motility by flagella, of magnetotactic bacterial cells along magnetic field lines. All known magnetotactic bacteria generally swim bidirectionally although some are known to "loop" while swimming. None exhibit run-and-tumble motility as do some nonmagnetotactic bacteria (e.g., *Escherichia coli*). Most magnetotactic bacteria swim

following an helical-like trajectory whose characteristics depends on the relative inclination of the magnetosome chain and the flagella, according to theoretical studies done on mono- and bi-flagellated bacteria.

Magnetotaxis is considered advantageous to bacteria in vertical chemical concentration gradients (e.g., O_2) in locating and maintaining an optimum position in the gradient because magnetotactic bacteria use the Earth's magnetic field lines as a fixed reference to swim, unlike other bacteria. Presumably, if a magnetotactic bacterium is displaced from its optimal position, it would use geomagnetic field lines to more efficiently return to its optimal position. Magnetotactic bacteria, after aligning along geomagnetic field lines, would have a one-dimensional search problem in locating their optimal position in a vertical chemical concentration gradient whereas nonmagnetotactic bacteria would have a three-dimensional search problem, presumably expending more time and more energy.

The original model of magnetotaxis stated that all magnetotactic bacteria had one of two possible swimming polarities: north-seeking and south-seeking. The swimming polarity depends ultimately on the direction of motion of the cell under oxic conditions. This was based on the observation that in the Northern Hemisphere, magnetotactic bacteria predominantly swim parallel to the magnetic field toward the north, hence the term north-seeking. In the Southern Hemisphere, the opposite was observed and south-seeking bacteria swim antiparallel to the field. Because, the geomagnetic field is inclined downward from the horizontal in the Northern Hemisphere and upward in the Southern Hemisphere, with the magnitude of the inclination increasing from the equator to the poles, the outcome of this situation is that in both hemispheres the bacteria swim downward toward the region of the sediment with little oxygen or no oxygen. In the original model, once a bacterium reached a layer of the sediment with suitable oxygen concentration, it would stop moving and possibly adhere to a sediment particle.

Two important observations were inconsistent with this magnetotaxis model: (1) the observation that north-seeking magnetotactic bacteria in pure culture (e.g., *Magnetococcus marinus* strain MC-1) form horizontal bands at certain positions below the meniscus in culture tubes containing an O_2 concentration gradient, instead of swimming persistently to the bottom of the culture tube; and (2) some populations of uncultured magnetotactic bacteria were observed in the water column in chemically stratified aquatic environments, not in the sediments. Should the original model be true, all magnetotactic bacteria would swim to the bottom of culture tubes and to the sediment in natural aquatic environments. An expansion of the magnetotaxis model was then proposed based on the observation that magnetotaxis appears to function in conjunction with aerotaxis. This is known as the magneto-aerotaxis model.

Magneto-Aerotaxis

Originally, two different magneto-aerotactic mechanisms were proposed: axial and polar magneto-aerotaxis. In axial magneto-aerotaxis, cells do not show a polar preference and the magnetic field defines the axis but not the direction of swimming. This mechanism is typical of cells of *Magnetospirillum* species grown in liquid media. Cells spontaneously reverse their swimming direction in an applied magnetic field. Thus, the distinction between north-seeking and south-seeking does not apply to axial magneto-aerotactic spirilla. Recent studies on cells of 12 strains of cultured magnetotactic bacteria of various morphotypes, including spirilla, in microcapillary tubes containing an O_2 concentration gradient and placed in a homogeneous magnetic field showed six different behaviors for north-seeking magnetotactic bacteria when the O_2 gradient and the magnetic field were parallel, and not simply polar and axial magneto-aerotaxis as described above. It was proposed from the results, that there are three general magneto-aerotactic mechanisms: axial, dipolar (formerly called polar) and unipolar magneto-aerotaxis.

In dipolar magneto-aerotaxis, the most common mechanism observed in natural populations of magnetotactic bacteria, cells show a polar preference in their swimming direction. The magnetic field provides both direction and axis for the magnetotactic behavior. This is based on experimental findings of the cultured coccus *Magnetococcus marinus* strain MC-1. In the magneto-aerotaxis model, magnetotactic bacteria can be either in an oxidized or in a reduced state. In the oxidized state, when in the oxic zone of a vertical concentration gradient of O_2 , cells swim downward. They do this by rotating their flagella counterclockwise (Fig. 10). However in the reduced state, their flagella would rotate clockwise and the bacteria would reverse direction without turning around (they would still be aligned along magnetic field lines) and thus move upward, again toward the optimal O_2 concentration. In this model, magnetotactic bacteria still benefit from having a fixed axis for swimming.

The dipolar magneto-aerotaxis model can be extended to redoxaxis in habitats in which spatially separated reservoirs of reductants and oxidants coexist. In these cases, some magnetotactic bacteria would swim into anoxic zones of their habitat to accumulate reduced compounds possibly as a source of electrons for growth (e.g., reduced sulfur compounds) and then swim back to zones in which oxidized compounds (e.g., O_2) are present and perhaps required for growth.

Unipolar magneto-aerotaxis is similar to the dipolar magneto-aerotaxis, although cells swim persistently in one direction (toward the anoxic region or toward the oxic region) using the geomagnetic field as a guide. Once the persistent anoxic unipolar magnetotactic bacteria reach an oxic region, they reverse their swimming direction, reaching the anoxic zone again and vice-versa.

There is evidence that magneto-aerotaxis does not explain the behavior of all magnetotactic bacteria particularly those in natural environments. For example, a population of mainly south-seeking magnetotactic bacteria (the barbell-shaped bacterium discussed in an earlier section) has recently been discovered in a chemically stratified environment in the Northern Hemisphere. In the Southern Hemisphere, a population of north-seeking magnetotactic bacteria was also characterized in a lagoon in the South Hemisphere. These microorganisms seem to represent a deviation from the magneto-aerotaxis model for magnetotactic bacteria as they were found in the anoxic zone of their environment and putatively swam in the theoretically "wrong" direction, that is, they

Fig. 10 Schematic drawing showing how magneto-aerotaxis may help magnetotactic bacteria to locate and maintain an optimal, preferred position in natural habitats with vertical chemical concentration gradients (e.g., O₂). See text for details.

had the “wrong” magnetic polarity. In these situations, if cells follow the polar magneto-aerotaxis principle, they would swim persistently to a less favorable/optimal environment.

For cells of *Magnetospirillum gryphiswaldense*, magneto-aerotaxis experiments showed that an increase of the geomagnetic field intensity 10-fold or a tilt of 45 degree of the magnetic field relative to the O₂ concentration gradient did not significantly change the magneto-aerotaxis efficiency, although it was drastically reduced when the magnetic field was null or when the tilt was 90 degree. These results show that magneto-aerotaxis efficiency is not proportional to the cosine of the tilt angle, as assumed by classical models of magneto-aerotaxis.

In both polar and dipolar magnetotactic bacteria, the swimming polarity can be switched from north-seeking to south-seeking and vice-versa by exposing cells to demagnetizing magnetic fields of 50 Hz and above 0.1 T, or even at pulses of 1 to 5 ms at about 0.07 T. These observations were used to show that magnetosome magnetite crystals are single-magnetic-domains. There is now evidence that redox gradients combined with manipulations of the magnetic field direction can also change the swimming polarity of magnetotactic bacteria. In cultures of *Magnetospirillum gryphiswaldense*, it has been shown that the swimming behavior of cells can be switched from axial to dipolar in the presence of O₂ concentration gradients and magnetic fields oriented parallel or antiparallel to the gradient. In addition, sudden increases in the local O₂ concentration results in the conversion of cells to the opposite polarity. Collecting and/or concentrating magnetotactic bacteria from mud and water samples using strong magnets can also reverse their swimming polarity and thus caution must be used in determining the polarity of magnetotactic bacteria in environmental samples. In addition, a high number of chemotactic receptor genes are present in many magnetotactic bacterial genomes (e.g., 56 genes appear to encode for chemotactic receptors in *Magnetospirillum gryphiswaldense* strain MSR-1) in comparison to other bacterial genomes (e.g., five genes encoding chemotactic receptors in *Escherichia coli*), possibly indicating that chemotaxis is more complex in magnetotactic bacteria possibly suggesting that the interaction between chemotaxis and magnetotaxis is also complex. Thus, additional models of magnetotaxis, possibly associated with chemical concentration gradients other than O₂ (e.g., sulfide), are likely needed to explain the behavior of some magnetotactic bacteria.

Magnetotactic Eukaryotes

A magnetotactic response was reported in some eukaryotic microbes (protists) collected from coastal areas. Transmission electron microscopy revealed intracellular iron-rich crystalline inclusions identical to bacterial magnetosome magnetite crystals in some of these organisms. Intact magnetotactic bacteria were not observed in the cells. Two possibilities exist for the origin of these magnetosomes. First, the protist itself might biomineralize magnetosomes. This seems to be the case for the magnetotactic euglenoid alga *Anisonema platysomum* found to be present in a marine habitat in Brazil. This protist produces rows of chains of bullet-shaped magnetosomes in an elaborate pattern along the long axis of the cell. The morphology of the crystals is uniform and the magnetotactic response is consistent with the magnetic polarity of magnetotactic bacteria from the same environment as they show a directional swimming preference in the magnetic field.

Second, bacteria-grazing protozoa may ingest magnetotactic bacteria and their magnetosomes, which may be stable or partially or fully solubilized. They might be incorporated into the cell or present for a short time in food vacuoles, the likely site for solubilization. This seems to be the case for certain biflagellates, dinoflagellates, and ciliates detected in coastal areas. The significance and implications of this, as well as details of protozoal grazing of magnetotactic bacteria, is discussed later. Regardless of the origin of magnetite or greigite crystals in protists, some of these eukaryotic microbes contain a significant amount of intracellular iron.

Geochemical, Geophysical, and Astrobiological Aspects of Magnetotactic Bacteria

Cultured magnetotactic bacteria are known to facilitate a number of important geochemical processes and thus it is likely they play important roles in these processes in natural environments. These include sulfide oxidation, sulfate reduction, denitrification, nitrogen fixation, and iron redox reactions (iron cycling) through magnetosome biomineralization and possibly through iron oxidation not related to magnetosome synthesis. In addition, all cultured marine strains are facultatively autotrophic through either the Calvin-Benson-Bassham or the reverse (or reductive) tricarboxylic acid cycles. The freshwater magnetospirilla show potential for autotrophy at least one species has been shown to grow autotrophically and as most appear to contain in their genomes an intact ribulose-1,5-bisphosphate carboxylase/oxygenase (RubisCO) gene, which encodes for one of the key enzymes in the Calvin-Benson-Bassham cycle. Thus magnetotactic bacteria have great potential in regulating important geochemical reactions and cycles involving several important elements including sulfur, nitrogen, iron, and carbon.

Protozoa are known to be important components of the marine ecosystems as the primary consumers of bacteria and recyclers of certain nutrients, including iron. Magnetotactic protists might play an important role in iron cycling either through direct biomineralization or through grazing on magnetotactic bacteria and solubilizing magnetosomes. Iron is a limiting factor in primary production in some oceanic and coastal areas. This element, which is often present in seawater in particulate and colloidal forms, can be digested in the food vacuoles of protozoans during grazing of particulate and colloidal matter. This process might generate more bioavailable iron for other species in the food chain. The chemical stability and thus the persistence of magnetosomes and magnetosome crystals depend on its surrounding environment. Magnetite magnetosomes appear to be quite stable in the bacterial cell possibly due to the magnetosome membrane and there is no evidence that magnetotactic bacteria can reuse iron in magnetosomes for another purpose even when cells are starved for iron. Is it possible for protozoans grazing on magnetotactic bacteria to make ingested magnetosome iron more bioavailable through solubilization? One possible mechanism of conversion of biologically unavailable forms of iron into more soluble forms is through the action of acidic food vacuoles on solid or colloidal forms of iron in protozoa. This has been observed to occur with colloidal iron and with greigite magnetosomes from magnetotactic bacteria.

The dissolution of greigite magnetosomes by the ciliate *Euplotes vannus* has been demonstrated in *in vitro* experiments. The ciliates ingested greigite-producing magnetotactic bacteria, the multicellular magnetotactic prokaryote discussed earlier, which became enveloped in food vacuoles known to have an internal acidic pH. Transmission electron microscopy (Fig. 11) and X-ray microanalysis of thin-sectioned ciliates showed that within the acidic vacuoles, the greigite crystals dissolved at different rates after the magnetosome membrane was digested. The experiments with *Euplotes* suggest that protozoans that graze on magnetotactic bacteria in natural environments are likely important in iron cycling as they may help to solubilize iron trapped in the magnetosomes, making it bioavailable to other organisms. The impact of magnetite magnetosome digestion by protozoans remains unknown, but, based on the experiments with greigite magnetosomes, there is potential for magnetosome magnetite to also be solubilized by protozoans.

A simple calculation may help estimate the potential of the recycling of magnetosomes produced by magnetotactic bacteria. Each multicellular magnetotactic prokaryote contains about 30 cells with approximately 100 magnetosomes per cell, which leads to each aggregate containing about 3000 magnetosomes. Using an average magnetosome size of 100 nm, which results in a cubic volume of 106 nm^3 , and a greigite density of 4.1 g/cm^3 , each multicellular unit contains an estimated total amount of $1.2 \times 10^{-11} \text{ g}$

Fig. 11 Transmission electron microscopy image of an ultra-thin section of a ciliated protozoan that has ingested a number of magnetotactic multicellular bacteria. The bacterial cells (white arrows) are in vacuoles where they appear to be in the process of being digested. Magnetosome clusters can be seen (dark arrows). The inset shows a high-magnification image of a cluster of magnetosomes in different degrees of dissolution. No magnetosome membrane is seen in heavily digested crystals (arrow); m, mitochondria; L, lipid inclusions.

of greigite that could potentially be solubilized within the ciliates and eventually released to the environment. Marine magnetotactic bacteria are known to reach population densities of 10^4 cells ml^{-1} in some natural environments. Taking into consideration the large amount of iron concentrated by magnetotactic bacteria in intracellular magnetosomes (10^{-13} to 10^{-15} g iron per cell) and their estimated population density, in some habitats, nanomolar concentrations of iron may be sequestered by magnetotactic bacteria and then solubilized by grazing protozoans that ingest them, thereby recycling significant amounts of iron.

Magnetotactic bacteria are considered to be a main source of the magnetization of sediments in a number of freshwater and marine environments. In many of these environments, magnetosome crystals, particularly magnetite, is released from dead, lysing cells and accumulate in sediments and persist relatively unaltered for long periods of time. In some cases, even magnetosome chains persist. Because magnetosomes are single-magnetic-domain particles, they form ideal carriers of paleomagnetic information as they cannot be demagnetized. Nanometer-sized magnetite grains have been recovered from a number of soils and lacustrine and modern and ancient deep sea sediments. In many cases, these particles were identified as biogenic by their shape and size, which were similar to magnetite crystals in magnetotactic bacteria and were therefore referred to as “magnetofossils.” Putative fossil magnetotactic bacterial magnetite crystals have been found in stromatolitic and black cherts from the Precambrian, some dating as far back as 2 billion years. If these crystals are actually from magnetotactic bacteria, they represent some of the oldest bacterial fossils on Earth. Many of the crystals, however, found in these rocks were partially degraded, showed indistinct edges, and underwent partial oxidation to maghemite. The crystals have been used as supporting evidence that free O_2 had begun to accumulate in the atmosphere before 2000 Ma and that the present intensity of the Earth’s magnetic field strength had appeared by 2000 Ma. If magnetosomes are biomineralized by protists or retained by protists after ingestion of magnetotactic bacteria, then these eukaryotes, like the magnetotactic bacteria, might also directly contribute to the magnetization of sediments.

The cuboctahedral crystal habit is the equidimensional form of magnetite and it is commonly found in inorganically produced magnetites. The elongated, nonequidimensional, pseudo-hexagonal prismatic and bullet-shaped forms of magnetite are very unusual. Both have been found in magnetic separates of sediments and it would seem only the latter elongated forms of magnetite might represent reliable magnetofossils of magnetotactic bacteria and could therefore be used as biomarkers of the past presence of magnetotactic bacteria.

The presence of ultrafine-grained magnetite, pyrrhotite, and greigite in the rims of carbonate inclusions in the Martian meteorite ALH84001 was considered one of the lines of evidence for life on ancient Mars. This meteorite, estimated now to be ~ 4.1 billion years old, contains magnetite crystals about 10–100 nm in size with cuboid, teardrop-shaped, and irregular morphologies. About 25% of the magnetite crystals present have an unusual morphology referred to as truncated hexa-octahedral, which is essentially the same morphology of magnetite crystals found in the marine magnetotactic vibrio, *Magnetovibrio blakemorei* strain MV-1.

The elongated magnetite crystals from *Magnetovibrio blakemorei* strain MV-1 have been studied in great detail and show a number of different distinctive properties putatively not found in inorganically produced magnetite crystals. These properties have been considered by some to be suitable criteria for the determination of whether magnetite crystals are biogenic or not. These properties include (1) narrow size range (a non-log-normal size distribution with the mean centered in the single-magnetic-domain size range); (2) restricted width-to-length ratios; (3) high chemical purity; (4) few crystallographic defects (crystals are generally defect-free with the exception of occasional crystal twinning); (5) crystal morphology with unusual truncated hexa-octahedral geometry; and (6) elongation along a specific crystallographic axis of the crystal. The 25% of the magnetite crystals in ALH84001 that resemble those of *Magnetovibrio blakemorei* seem to fit the above criteria. However, there are several other hypotheses regarding the origin of the magnetite crystals in meteorite ALH84001 that do not involve biology but only chemistry. Thus, some disagree that these criteria are robust enough to distinguish between biogenically and abiogenically produced magnetite crystals and so the debate continues.

Biotechnological Applications of Magnetotactic Bacteria, Magnetosomes, and Magnetosome Crystals

The controlled biomineralization of magnetosomes and their single-magnetic-domain particles of relatively high structural perfection and purity as well as consistent species-specific crystal morphologies suggest that there is great potential for biotechnological applications. In general, the amount of magnetite and magnetosomes from magnetotactic bacteria is relatively low especially considering the amount needed for specific applications. Thus, in order to produce enough cells, magnetosomes, and magnetite crystals for these applications, cells must be grown in mass culture where the conditions for growth and magnetite synthesis must be optimized. This was a major obstacle to research in this area for years. In the last decade, techniques including those involving continuous culture methods have been devised for the successful mass culture of various *Magnetospirillum* species and *Magnetovibrio blakemorei* strain MV-1. For example, for *Magnetospirillum gryphiswaldense* strain MSR-1, a chemostat culture technique based on pH-stat feeding allowed the production of a high cell density in an auto-fermentor. Using this technique, it was possible a magnetosome yield of about 83 mg L^{-1} and a productivity of about $55 \text{ mg L}^{-1} \text{ day}^{-1}$.

Cells of magnetotactic bacteria have proven useful in many interesting applications. For example, living north-seeking cells of polar magnetotactic bacteria have been used to determine south magnetic poles in meteorites and rocks containing fine-grained ($< 1 \mu\text{m}$) magnetic minerals. Cells of magnetotactic bacteria have also been used in a number of medical applications including the magnetic separation of cells such as granulocytes and monocytes that phagocytized magnetotactic bacteria. Recently, the possibility of using magnetotactic bacteria in the removal of heavy metals and radionuclides from wastewater was investigated. The advantage here again is that if the cells can take up significant amounts of heavy metals they can be separated magnetically and the contaminant can be eliminated from an aquatic system. Cells of the sulfate-reducing magnetotactic bacterium, *Desulfovibrio magneticus* strain RS-1, have been used in cadmium recovery using magnetic separation. A recently described application is the trapping of magnetotactic bacteria using a commercial magnetic recording head. This method may be useful in counting

magnetotactic bacteria cells in water samples or to detect magnetically labeled bacteria or magnetosomes. Magnetotactic bacteria have been manipulated as nanorobots through a directional magnetic field that force them to push 3 μm beads along preplanned paths and creating structures as pyramids.

Magnetosomes contain single-magnetic-domain crystals that have been shown to have useful magnetic and physical properties. In addition, the organic phospholipid membrane that envelopes the crystals allows for the immobilization of biological molecules such as nucleic acids or nonmagnetosome proteins on their surfaces. Magnetosomes have thus been used in the immobilization of specific enzymes, some of which show higher enzymatic activity when attached to magnetosomes than when attached to commercially synthesized magnetite particles. Antibodies linked to magnetosomes or magnetosome crystals have been developed and have proven useful in various immunoassays involving the detection of allergens, certain cancer cells, and the quantification of immunoglobulins.

Magnetotactic bacterial magnetite crystals have been used to detect single nucleotide polymorphism based on a fluorescence resonance energy transfer technique in which double-stranded labeled DNA is synthesized by PCR and immobilized to the magnetite crystals hybridize to target DNA and a fluorescence signal is detected. Magnetosome membrane proteins on the surface of bacterial magnetite particles have been used as anchor proteins for the assembly of foreign proteins on the surface of magnetite magnetosomes. These so-called protein displays have been designed using the magnetosome membrane proteins MagA, MpsA, Mms16, and Mms13 (MamC). Magnetotactic bacterial magnetite particles have been modified using compounds such as hyper-branched polyamidoamine dendrimers or amino silanes for the extraction of DNA. Biotin attached to a monolayer-modified substrate was detected by streptavidin immobilized to bacterial magnetite particles using a magnetic force microscope showing the potential of magnetosomes in the detection of biomolecular interactions in medical and diagnostic analyses. In the case of antitumor treatments, magnetosomes have been used as potential drug carries and as targets for hyperthermia. Finally magnetosomes and/or magnetosome crystals are being currently used to attempt to enhance magnetic resonance imaging (MRI).

Perspectives

Magnetotactic bacteria and magnetosomes are a subject of an active and interdisciplinary field of research that includes topics such as microbiology, cell biology, geomicrobiology, palaeomagnetism, microscopy, biomineralization, biophysics, and biochemistry to name a few. New and exciting findings are constantly being reported on these microorganisms. New directions will come that will inspire research groups in this highly multidisciplinary field of microbiological research.

Glossary

AOM Anaerobic oxidation of methane, carried out by a consortium of anaerobic methane-oxidizing (ANME) Archaea and sulfate-reducing bacteria (see 'gas hydrates').

Basalt Gray to black extrusive volcanic rock, forming the basement underneath the marine sediments (see 'marine basement').

Cretaceous shales Organic-rich marine sediments deposited under oxygen-free conditions in the Cretaceous period 84–140 million years ago (see 'sapropel').

Crustal fluid Circulating water in the basement rock.

Gas hydrate Crystalline water-based solids physically resembling ice, in which gases (typically methane) are concentrated inside 'cages' of water molecules.

Igneous rocks Rocks formed by solidification of cooled magma.

Lithotrophy/lithotrophic organisms Use of an inorganic substrate (e.g., H_2 , NH_4^+ , Fe^{2+} , H_2S) to obtain reducing equivalents for aerobic or anaerobic respiration.

Marine basement Oceanic crust; part of the Earth's crust formed at the mid-ocean ridges that becomes buried by sediment with age (see 'basalt' and 'crustal fluid').

Pyrolysis The chemical decomposition of organic materials by heating in the absence of oxygen or any other reagents.

Sapropel Periodically occurring organic matter-rich sediment layers of the Eastern Mediterranean and Black Sea that were deposited under conditions of bottom water anoxia (see 'Cretaceous shales').

Subsurface The upper boundary of subsurface sediments is not clearly defined. A feasible definition is the anoxic layers beneath the zone of bioturbation by borrowing macrofauna.

Weathering Decomposition of rocks, soils, and their minerals. Can be driven chemically or by microorganisms.

Defining Statement

Marine sediments cover about 70% of the Earth's surface and contain the largest reservoir of organic matter. These sediments have been found to be a major microbial habitat to at least 2.5 km depth. Specific prokaryotic groups able to cope with extreme limitation dominate deep sediments, using ancient organic matter and geosphere energy sources.

Introduction and Background

Oceans cover around 70% of the surface of the Earth and are underlain by extensive sediments with an average depth of about 500 m, but up to 10 km deep in places. Within the oceans between 5 and 10×10^9 tons of particulate organic matter are constantly sinking, but only about 1 % of gross photosynthetic production finally reaches the sediment surface. Most of this sedimentary organic matter is degraded within the uppermost sediment layers and only a very small fraction survives and is buried. However, this buried organic carbon represents one of the largest carbon reservoirs on Earth ($15,000 \times 10^{18}$ g). On geological timescales the burial of organic matter had a significant effect on the global biogeochemical cycles, allowing atmospheric oxygen levels to increase and acting as a sink for carbon dioxide and hence exert significant influence on climate and the habitability of the planet.

[☆]*Change History:* September 2018. Henrik Sass and Gordon Webster have completely rewritten and updated the text. All paragraphs have been rewritten. The further reading list was updated and modified. Outdated information has been removed, including Tables 1–3. Fig. 1 has been updated using the latest data available and replaces the old Fig. 1. Figs. 2, 3 and 7 have been removed. Previous Fig. 4 becomes new Fig. 5; previous Fig. 5 becomes new Fig. 4; Fig. 6 stays as it is. Previous Fig. 8 becomes new Fig. 2 and previous Fig. 9 becomes new Fig. 3.

This article is an update of R.J. Parkes, H. Sass, Deep Sub-Surface, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 64–79.

The oceans have an average depth of 3800 m and thus an average bottom pressure of 38 MPa (this is about 380 times higher than atmospheric pressure), while at the maximum ocean depth (11,000 m, Marianas Trench) pressure reaches 110 MPa. Pressure increases further with depth into the sediments. This high pressure in deep-sea sediments in combination with low temperatures (around 2°C at the sediment surface), little organic matter to provide an energy source, and with porosity and nutrients decreasing with depth, resulted in conditions that were once considered to be too extreme for life. Subsurface sediments were usually not even considered as a possible habitat. Researchers investigating the presence of microorganisms in deep-sea sediments by cultivation-based methods in the 1950s seemingly confirmed this absence of life. As no microorganisms were cultured from the deepest (7.47 mbsf, meters below sea floor) and oldest layers, they then concluded that they had reached the lower limit of the biosphere. Hence, almost nothing seemed to happen in deep subsurface sediments until temperature (average increase 30 K per km) reached 100–150°C at a few kilometers depth, and when buried recalcitrant kerogen (preserved macromolecular organic matter) pyrolyzed to produce oil and gas. However, more recently a number of findings led to question whether subseafloor sediments are really devoid of life: It turned out that only a small fraction of environmental bacteria can be grown in the laboratory on standard microbiological media, questioning the validity of previous results. The discovery of hyperthermophilic microorganisms thriving at temperatures above 100°C significantly extended the temperature range for life and hence the potential depth range. In addition, geochemical studies found indications for biogenic methanogenesis some tens of meters beneath the sediment surface, far below the previous 'lower limit' of the biosphere.

Comprehensive microbiological investigations since 1986 have consistently shown the presence of significant prokaryotic populations in marine subsurface sediments. The presence of these prokaryotes was confirmed by a combination of different methods directly corroborating each other, including microscopic detection, presence of culturable prokaryotes (including anaerobes), direct activity measurements (using radiolabeled substrates), presence of high molecular weight prokaryotic DNA, RNA and lipid biomarkers, and correlation with geochemical changes characteristic of prokaryotic activity. Population estimates vary among different researchers, depending on which data are used for their calculations, but are generally so large that global estimates suggest the marine deep biosphere accounts for between 1% and 30% of all biomass and for up to 70% of all prokaryotes on Earth. However, the marine deep subsurface is part of a global deep biosphere that includes other deep subsurface environments such as aquifers, consolidated Cretaceous shales, igneous rocks, glaciers and ice sheets, lignite and coal formations, mud volcanoes, and marine and terrestrial oil reservoirs.

Prokaryotic Cell Concentrations and Distributions in Subseafloor Sediments

A major concern for early subsurface microbiology research was potential contamination of deep sediments with prokaryotic cells from shallow sediment layers or from seawater during the coring process. Chemical tracers and fluorescent microspheres (0.5 µm diameter to mimic cells) have been added to drilling fluids to directly detect potential contamination during the drilling process. This approach has confirmed that contamination is usually restricted to the outer layers of the core and thus contamination can be avoided by the normal practice of sampling from the core center.

Microbial cells in sediments are usually quantified after staining with a DNA dye and by counting recognizable cells using an epifluorescence microscope. Counting cells directly within fixed sediment slurries has a detection limit of about 10^4 cells cm^{-3} , and hence, even if no cells are detected a population between zero and 10^4 cells cm^{-3} may actually be present and nonetheless represent a considerable prokaryotic community. Recently, a number of modifications to the original approach have increased sensitivity, for example detachment of cells from sediment particles, allowing larger volumes to be analyzed. However, these methods still rely on subsequent quantification by epifluorescence microscopy or flow cytometry.

Sediment cell counts generally decrease with depth (Fig. 1), a correlation that can be explained by the rapid degradation of easily degradable organic matter, leaving increasingly recalcitrant material behind for microorganisms in deeper layers. It may therefore not be surprising that in most sediments cell numbers decrease exponentially with depth, and although at a few hundred meters depth cell counts have decreased about 1000-fold, in some sediments more than 10^6 cells cm^{-3} are still present which represents still a significant amount of biomass. Cell numbers at the sediment surface can vary substantially between sites and the amount of microbial biomass seems to directly correlate with the amount of organic matter input into the sediment. The latter is controlled by the trophic state of the water column, and primary production, but also by water depth and hence sedimentation time, during which the organic matter is exposed to degradation by pelagic microorganisms. Sediments with a high organic matter input (e.g., Peru margin, 150 m water depth) can have cell numbers at the surface around 10^9 cells cm^{-3} or significantly higher (Baltic Sea), whereas numbers in surface sediments of the ultra-oligotrophic South Pacific Gyre (more than 4000 m water depth) are almost 1000-times lower. This suggests that organic matter controls overall numbers of subsurface prokaryotic cells and represents their main energy supply.

The lower boundary of the deep biosphere has not been found so far. Viable cells were detected in coal layers over 2000 mbsf, and a number of IODP cruises detected cells through the entire sediment column and into the underlying oceanic crust. This suggests that living cells will be present as long as the physicochemical conditions permit (the current upper temperature limit for life is 122°C). It may be surprising to find cells in basaltic rocks, but their densities appear to be low (up to 10^5 cells cm^{-3}) and cells mostly confined to crustal fluids, fractures, and altered glassy basalts. However, because of the large volume of the oceanic crust (10^{18} m³), the crustal biosphere is estimated to represent at least 1% of the global biomass.

Deep Biosphere Hot Spots

Deep sediments with elevated cell numbers can be seen as deep biosphere 'hot spots'. There are, however, different reasons for these increased cell numbers. As previously described, prokaryotic populations are consistently elevated in layers high in organic matter despite the latter being often millions of years old. One example is sapropels that are discrete organic matter rich (up to 30% OM) layers that occur in some marine sediments, including the Mediterranean where they alternate with hemipelagic carbonate-rich sediments. When compared to these 'normal' hemipelagic sediments, sapropels showed significantly elevated cell numbers and strongly enhanced potential activities (e.g., exoenzyme activity and glucose degradation). The presence of such discrete zones of high cell concentrations and the preservation of individual sapropel layers also demonstrates that drilling disturbance during sample collection is minimal.

More numerous than the discrete sapropel layers are the high organic matter layers of Cretaceous shales, that were deposited some 84–140 Mya during major oceanic anoxic events, that resulted in enhanced global accumulation of sedimentary organic matter. Almost 100 Mya after their deposition these sediments still provide substrates for continuing prokaryotic activity not only in deep marine sediments (e.g., Equatorial Atlantic, Demerara Rise) but also when uplifted onto land. However, these shales are often highly compacted by the uplifting process and porosity and permeability are low. This restricts organic matter degradation within the shales to fermentative processes with the produced organic acids and hydrogen slowly diffusing into adjacent more permeable sediments (Fig. 2) where oxidation can be completed using electron acceptors supplied to the more permeable layers. This has been shown for lignite- or clay shale-sandstone interfaces where prokaryotic activity and cell numbers are clearly elevated (e.g., Waikato coalfield, New Zealand and Cerro Negro, New Mexico).

Cretaceous shales also have high petroleum generation potential when deeply buried. When temperatures reach 100–150°C thermogenic breakdown of kerogen produces oil and gas. Kinetic modeling predicts increasing kerogen reactivity with depth and abiological thermogenic processes are confirmed *in situ* by increases in methane and ethane. However, before temperatures for thermal breakdown are reached, kerogen reactivity already incrementally increases, potentially enabling its utilization by

Fig. 2 Schematic of prokaryotic metabolisms and interactions in subsurface, interbedded clay/Cretaceous shale and sand layers.

prokaryotes which means that prokaryotes are present when the thermal breakdown starts, as indicated by the presence of cells and intact phospholipids (Fig. 3). This demonstrates an overlap of biogenic and thermogenic processes in deep, hot sediments and the potential for high-temperature processes to feed the base of the deep biosphere. Thermogenic breakdown of kerogen produces a range of potential substrates for prokaryotes including low molecular weight hydrocarbons, organic acids, and hydrogen. Likewise, many subsurface oil reservoirs have considerable prokaryotic activity. In some high-temperature (70–110°C) North Sea oil reservoirs prokaryotic activity is so high that between 3 and 16 kg of prokaryotic cells is expelled per day with production fluids.

Gas hydrates contain globally twice the amount of carbon as other fossil fuels combined. They are only stable at low temperatures and high pressures, conditions typical for most marine subsurface sediments where a zone of gas hydrate stability exists. However, for the formation of sufficiently large quantities of methane to form hydrates, sulfate and other electron acceptors need to be depleted. Therefore, methane hydrates are usually found in relatively deep sediments that are organic matter rich, for example those underlying upwelling regions. Above the stability zone, gas hydrates are unstable due to low pressures and beneath

Fig. 3 Deep biosphere interaction with high-temperature thermogenic processes in Nankai Trough Sediments, Pacific Ocean. Left panel: Curves with crosses and dots (representing different sediment samples) show modelled estimates of increasing organic matter (kerogen) reactivity (as % transformation into volatile hydrocarbons) and measured rates of prokaryotic methanogenesis, relative to sediment depth (mbsf). Right panel: Depth distributions of ethane (circles), methane (diamonds), and total prokaryotic cells (triangles). The gray arrowheads indicate depths where intact phospholipids were detected. Temperature range of sediments extreme right. Reproduced from Horsfield, B., Schenk, H.J., Zink, K., et al., 2006. Living microbial ecosystems within the active zone of catagenesis: Implications for feeding the deep biosphere. *Earth and Planetary Science Letters* 246, 55–69.

due to high temperatures that cause hydrates to melt. Hence, above and below the gas hydrate zone, free porewater methane concentrations can be elevated and potentially stimulate anaerobic oxidation of methane (AOM) (Fig. 4). For this, however, an electron acceptor needs to be available which usually is sulfate. Sulfate-methane transition zones (SMTZ) are characterized by a general stimulation in prokaryotic activity and by elevated cell numbers (Fig. 4). While the upper SMTZ is usually the depth where sulfate is depleted, a lower SMTZ beneath this can be found in areas where sulfate is supplied to the sediments by deep fluid flow, like in sediments of the Peru Margin. Cell numbers at this deep SMTZ (at about 90 mbsf) are as high as at the sediment surface. Microbial community composition showed a significant change at this depth indicating that the deep sediment prokaryotic communities here are active and dynamic, as opposed to just being dormant. In some deep sediments nitrate may also be found from the stimulation of nitrification within the crust. In addition to electron acceptors, deep fluid flow can also provide substrates/electron donors like hydrogen or organic compounds synthesized by abiotic reactions between seawater and basement basalts at temperatures between about 100 and 300°C.

Diversity of Subsurface Prokaryotes

Early molecular surveys of deep subsurface sediments revealed a microbial community that strongly differed from that of surface sediments. The shift from a community dominated primarily by *Proteobacteria*, *Actinobacteria* and *Bacteroidetes* to a community consisting of novel phylotypes typical for subsurface sediments was usually found between one and a few meters into the sediment. The dominant bacterial groups in the deep biosphere were found to be certain subphyla of the *Chloroflexi*, and the *Gammaproteobacteria*, and the candidate phylum *Atribacteria*. These can be detected in the majority of subsurface sediments and represent the majority of bacterial phylotypes. *Deltaproteobacteria* are also widespread but numerically not as numerous. While the detected *Gammaproteobacteria* in most cases are fairly closely related to cultured organisms, the majority of the *deltaproteobacterial* sequences are only distantly related to known organisms. Other bacterial groups, e.g., *Alphaproteobacteria*, *Bacteroidetes*, *Planctomycetes*, the *Aminicenantes* (candidate division OP8), and the NT-B2 cluster were less frequently detected.

Like for the Bacteria, most archaeal sequences found in deep subsurface sediments were generally not closely related to cultured organisms. The molecular surveys targeting Archaea revealed an unexpected high diversity of *Bathyarchaeota*, *Euryarchaeota*, *Thaumarchaeota* and *Lokiarchaeota*. In almost all subsurface sediments studied so far, the *Bathyarchaeota* (including the Miscellaneous Crenarchaeotal Group, MCG) is by far the dominant group. Several other groups are also widespread but numerically less abundant, for example, the thaumarchaeotal Marine Group I (MG-I), the lokiarchaeotal Deep-Sea Archaeal Group (DSAG), and the euryarchaeotal *Hadesarchaea* (including the South African Gold Mine Euryarchaeotal Group, SAGMEG), Marine Benthic Group

D (MBG-D), and Terrestrial Miscellaneous Euryarchaeotal Group (TMEG). Other archaeal groups (e.g., *Thermococcales*, *Archaeoglobales*, deep-sea hydrothermal vent euryarchaeota) are less frequently found and represent a small percentage of all sequences.

Sulfate-reducing and methanogenic prokaryotes are the most important terminal oxidizers in anoxic environments and were expected to be amongst the dominating physiological groups present in subsurface sediments. However, known sulfate-reducing genera were very rarely detected by molecular biological approaches, even if primers specific for sulfate-reducing prokaryotes were used. Methanogens were generally more often detected with the most abundant sequences affiliating with the well-known genera *Methanosarcina*, *Methanobrevibacter*, and *Methanococcoides*.

These early molecular studies were restricted by problems in DNA extraction and purification and by the resolution of the methods used. Clone libraries and denaturing gradient gel electrophoresis (DGGE) were the most commonly used methods and allowed only a limited number of sequences to be identified. However, new methods that became available during the last decade, particularly high-throughput sequencing and metagenomic analysis, significantly increased phylogenetic resolution, allowing the identification of up to several thousand operational taxonomical units (OTUs) within a single sample. This improved detection limit and resolution. It turned out that those OTUs that were novel and considered specific for subsurface sediments (e.g., *Chloroflexi*, *Atribacteria*, *Bathymarchaeota*, or *Hadesarchaea*) are by no means restricted to the deep, but also present in near-surface environments, although representing here only a minor fraction of the total community. However, these OTUs represent a core set of prokaryotes that are present throughout the entire sediment column and becomes dominant at depth, whereas 'typical' surface phylotypes disappear. This was seen as an indication that these subsurface OTUs are particularly well adapted to energy limitation.

The model of a residual ('left over') community is supported by the low growth rates observed in subsurface sediments. In a coastal subsurface sediment average cell generation time increased from 0.2 to 40 years along the upper seven meters. If generation times in these organic matter rich sediments are already so long, they can be expected to be even higher in deeper or organic matter poor sediments. This seems to be confirmed by reports that indicate generation times of a few hundred years in laboratory incubations of ultradeep (over 2000 mbsf) sediments.

Prokaryotic Metabolic Processes and Energy Sources

The metabolism of subsurface prokaryotes is considerably diverse and reflects the range of prokaryotic activities found in near-surface sediments (Fig. 5). The major substrate for subsurface prokaryotes is recalcitrant macromolecular organic matter, that is

Fig. 5 Schematic of prokaryotic processes of organic matter degradation in subsurface sediments.

initially hydrolyzed and, once oxygen is removed, fermented into low molecular weight compounds, particularly acetate and other organic acids, and hydrogen. These fermentation products are then oxidized by the terminal oxidizers using a range of electron acceptors (Fig. 5) in order of decreasing energy yield: Nitrate followed by manganese oxides, iron oxides, sulfate; and carbon dioxide (methanogenesis). In shallow sediment with its high cell densities anaerobic respiration seems to follow this predicted sequence with depth. In deep sediments, however, cell densities, organic matter contents and reaction rates are much lower, and minerals containing metal oxides with different reactivities may be available. This allows a number of anaerobic reactions to occur simultaneously (Fig. 5), with sulfate reduction and methanogenesis considered to be the major terminal oxidation processes in subseafloor sediments.

A special subset of macromolecular organic matter is necromass. As shown above cell numbers significantly decrease with depth and these disappearing cells serve as a potential substrate for the surviving *in-situ* community. The role of necromass is disputed with some studies suggesting that it is only important in the upper sediment layers, whereas other studies estimate turnover times and contribution to sediment metabolism for thousands of years and suggest a significant role for necromass in maintaining subseafloor life.

Hydrogen appears to be a particularly important substrate as it can diffuse effectively within sediments, eliminating the need for prokaryotes to actively move toward substrates. Hydrogen is a major fermentation product, but in deep sediments and the oceanic crust hydrogen can also be produced from inorganic reactions. This includes radiolysis of water by the decay of radioactive minerals and, particularly as temperatures increase with sediment depth, weathering of iron silicates. More recent studies suggest that elemental hydrogen can be produced even from silicate minerals, which depends on mechanochemical processes, and is stimulated by microbial activity. Abiological hydrogen formation and its utilization under anoxic conditions is extremely important, as it provides the potential for autotrophic prokaryotic processes and indicates the potential for some subsurface prokaryotic habitats being independent of photosynthetically produced organic matter (Slime – subsurface lithotrophic microbial ecosystem).

While hydrogenotrophic methanogenesis is well documented, evidence for homoacetogenesis, a process considered typical in deep freshwater lake sediments and in animal intestines, has only recently been found in deep sediments. Homoacetogenesis uses hydrogen and carbon dioxide to form acetate which provides a similar amount of energy to hydrogenotrophic methanogenesis. It has recently been implied that acetate can be used in the formation of both ethane and propane. Interestingly, these compounds have previously been considered to be of thermogenic origin and their potential prokaryotic origin suggests a wider microbial role in geochemical processes in deep marine sediments.

In deep coal-bearing sediments (over 2000 mbsf) methylotrophic methanogenesis was detected but surprisingly also heterotrophic methylotrophy was found (i.e., the oxidation to carbon dioxide). Methylotrophy uses one-carbon compounds, e.g., methylamine or methanol, but also methyl groups connected to larger molecules. Some of the methylotrophic substrates are released during kerogen maturation at elevated temperatures as volatiles. What acts as electron acceptor during the heterotrophic methylotrophs is unclear.

Analysis of the subsurface transcriptome seemingly corroborated organotrophy as the major energy metabolism in the marine deep biosphere. In sediments of the Peru Margin most RNA transcripts were of genes involved in the anaerobic metabolism of proteins, carbohydrates and lipids. Genes involved in cell growth and division were usually only found in layers with peaks in cell numbers. This is hardly surprising since subseafloor microbes are living under severe energy constraints. The subseafloor biosphere is a habitat that is under severe energy limitation and microorganisms present need to make use of any potential substrate available. It is likely that most of the *in-situ* microbial community has insufficient energy to even provide conventional amounts of energy for cell maintenance considering the large cell numbers present. However, subseafloor prokaryotes may be well adapted to their habitat where energy supply is on geological timescales. In addition, there may be a greater range of energy sources available than we are currently aware of.

The phylogenetic diversity of the yet-to-be-cultured bacterial and archaeal groups, for example the *Chloroflexi*, *Atribacteria*, *Aminicenantes*, *Bathy-* and *Thaumarchaeota*, suggests that each of these phyla harbors a wide range of metabolic types. This also is to be expected as they form an anaerobic foodweb in which the different roles need to be occupied. *Bathyarchaeota*, for example, possess the genes for the extracellular hydrolysis of proteins and amino acid fermentation. The genomes of *Atribacteria* showed potential for fermentative and syntrophic metabolism, but no indication for a respiratory chain as it would be required for aerobic and anaerobic respiration. The *Chloroflexi* is the only of these phyla that contains a number of families with cultured representatives. These cultures use anoxygenic photosynthesis, fermentation or reductive dehalogenation as energy metabolism. Single cell genomes of *Chloroflexi* indicated in addition the ability for lithotrophic growth and the reductive acetyl-CoA pathway, which is involved in homoacetogenesis. The potential for acetogenic growth and methanogenesis has also been found in cells belonging to the *Bathyarchaeota*.

Possible Contribution of Endospores to the Deep Biosphere

Many members of the bacterial phylum Firmicutes are able to form spores, resting stages that are inactive, strongly dehydrated, and highly resistant to environmental stresses. The stability and resistance of spores may help to explain the absence of spore-forming bacteria in molecular surveys, as it has been shown that most nucleic acid extraction procedures do not include spores, and that these require a much harsher treatment. Spores do contain enough energy for germination and are specifically adapted to quickly respond to substrate availability and formation of a vegetative cell able to replicate. When fresh *Desulfotomaculum* cultures,

containing either only vegetative cells or spores, were analyzed by dilution culturing, the spores showed almost 100% culturability, which was three to four order of magnitude higher than that of the vegetative cells. Therefore, spores may be able to easily outgrow other organisms after transfer to microbiological media, explaining their repeated isolation from subsurface sediments. As they do not exhibit active metabolism and do not require energy, it can be expected that they accumulate during sediment burial. Estimation of endospore numbers in deep marine sediments using the endospore-specific biomarker dipicolinic acid (DPA), suggested that spores are present in similar numbers to vegetative cells. However, what happens to these spores during extended burial is unknown; whether they degrade and contribute to necromass or survive and eventually germinate when conditions are favourable.

Cultivation of Deep Biosphere Prokaryotes

Cultivation efficiencies in subsurface sediments are generally very low, in most cases less than 0.1% of the cells can be stimulated to grow in microbiological media. This low culturability might be explained by the strongly energy-limited nature of deep sediment prokaryotes. Starved cells are often severely harmed (substrate shock, substrate-accelerated death) by a sudden exposure to high substrate concentrations as present in most standard microbiological media. Higher viable counts were obtained in more active layers, like sapropels or with deep layers that receive fluids from the underlying ocean crust that supply fresh growth substrates. In these layers up to 3% of all cells were stimulated to grow. However, this 'culturability' is still one order of magnitude lower than in coastal surface sediments when the same media are used.

Isolates obtained from deep subsurface sediments so far belong mostly to the alpha, beta, gamma, delta, and epsilon subgroups of the *Proteobacteria*, to the *Firmicutes*, *Actinobacteria*, and *Bacteroidetes* (Fig. 6). Although these are the same phyla as obtained from marine surface sediments, cultured diversity in subsurface sediments is generally lower. This reflects the decreased diversity with depth and the presence of a core microbial community found by molecular biological methods. Microorganisms isolated from these deep sediments must be able to survive under energy limitation, but to switch to fast growth if conditions change, like in microbiological medium. This resilience and longevity have been demonstrated for members of *Actinobacteria* (*Micrococcus*) and *Firmicutes* (*Bacillus*) that have been isolated from several million years old amber.

The presence of some of the cultured genera in subsurface sediments, for example, relatives of the alphaproteobacterium *Rhizobium radiobacter*, or the gammaproteobacterial genera *Pseudomonas*, *Halomonas*, and *Acinetobacter*, has also been confirmed by molecular biological techniques. For example, by quantitative real-time PCR it was shown that *R. radiobacter*-like bacteria can

Fig. 6 Phase contrast micrographs of bacterial isolates from Eastern Mediterranean sapropels (a–c) and carbon-poor hemipelagic sediment layers (d–e). (a) *Halomonas* sp. S6BA, (b) *Alteromonas* sp. S8FS1, (c) *Bacillus* sp. S6BB, (d) *Micrococcus* sp. SM3, (e) *Clostridium* sp. S01.

represent up to 5% of the *in situ* microbial community within Eastern Mediterranean sapropels. The presence of some of these cultured bacterial types in deep sediments, however, seems surprising, particularly for bacteria related to the putative soil bacterium *Rhizobium*, but these isolates grew well in marine medium under anoxic conditions, indicating that they may actually thrive in the deep sediments. These 'deep' bacteria, however, show only little differences to their surface counterparts in standard physiological tests (e.g., substrate tests, temperature range) and currently it is not clear what allows them to thrive or survive in deep sediments.

Cultivation-based studies have been widely criticized for not reflecting the actual *in-situ* diversity by missing the dominant phylotypes. One reason may be that the supposedly slow-growing subsurface prokaryotes are overgrown by opportunistic fast-growing bacterial types like some *Proteobacteria* or that they fail to form visible colonies. However, although there are no pure cultures of the subsurface *Chloroflexi* and *Atribacteria*, members of both phyla have been successfully enriched and maintained for extended periods of time in the laboratory. Since some *Chloroflexi* were growing in 'typical' anoxic microbiological media, a fermentative metabolism appears likely, which has been confirmed by single-cell genome analysis.

Physiological Adaptations of Deep Biosphere Isolates

Generally, there is relatively little information available about the physiological adaptations of deep subsurface organisms to their habitat due to the low number of fully characterized isolates. However, a few isolates have been fully investigated and may have characteristic adaptations for deep sediments (Table 1). Some of these isolates have an extraordinary broad temperature range for activity and growth, such as *Desulfovibrio profundus* covering a span of 15–65°C. This can be seen as a prerequisite to colonize large parts of the deep biosphere, since temperature increases with depth. As pressure increases with water and sediment depth, it is obvious that bacteria in subsurface sediments have to be pressure-tolerant. As an example, the optimum pressures of sulfate-reducing bacteria (e.g., *D. profundus*) from subsurface sediments of the Japan Sea reflect well the *in-situ* pressures as the isolates show no decrease in activity between atmospheric pressure and 20 MPa and are still active at pressures between 30 and 40 MPa. However, to date, all samples used for the enrichment and isolation of sulfate-reducing bacteria from subsurface environments have been decompressed during sampling and isolates obtained under atmospheric pressure, thereby potentially selecting for less barotolerant types. Although sampling devices can be recovered slowly to reduce the speed of pressure change, bacteria may still not be able to adapt quickly enough, and barophilic prokaryotes might still be damaged. Recently, coring and sediment handling systems that constantly maintain high pressures (e.g., DeepIsoBug) have been developed. These have been used to enrich microorganisms without decompression from gas hydrate containing sediments from a range of sites and the resulting cultures compared to those that were obtained with depressurization during core recovery. Both assays (undecompressed and decompressed) resulted in the enrichment of similar phylotypes. However, none of the sites sampled was deeper than 2000 m (estimated water pressure 20 MPa) and it seems likely not deep enough to see an effect of decompression during sample recovery.

Many of the isolated Bacteria obtained from subsurface environments are facultative anaerobes. At first sight, this may seem surprising, as subsurface sediments are generally anoxic. However, due to the low metabolic activities and consequently low production of reduced compounds like hydrogen sulfide, the redox potential in many deep-sea and subsurface sediments is not highly reduced. For example, in the Mediterranean Sea nitrate, oxidized manganese, or iron species are present at least as deep as the sapropel S1, which is approximately 12,000 years old. In some abyssal sediments, for example within the South Pacific Gyre, organic matter degradation rates are so low, that oxygen is only depleted several meters below the sediment surface, if at all, and no truly anoxic conditions establish anywhere in the sediment column. In addition, deep circulation of fluids may provide oxidants to subsurface sediments.

Significance of the Deep Biosphere

Estimates of the magnitude of the seafloor biosphere are up to 30% of all biomass on Earth. This deep biosphere must have a profound effect on the global biogeochemical cycles, by controlling the fate of sedimentary organic matter, but particularly by affecting deep and long-term processes previously considered to be purely geological. Prokaryotic activity probably continues with

Table 1 Pressure, temperature and salinity range for growth of some bacterial and archaeal isolates from marine subsurface sediments

depth until maximum temperatures are reached (currently at 122°C). This means that biosphere processes overlap with geosphere processes, and may occur even within the 'oil window' (100–150°C). Prokaryotes gain additional energy from these thermogenic degradation products and may make a significant contribution to methane gas reserves in the process. However, deep microbial activity can both produce and consume methane, contributing to the formation or dissolution of gas hydrate deposits. Sediments around gas hydrates are one of several subseafloor 'hot spots' characterized by elevated microbial activity and biomass. Deep sediments require physiological and biochemical adaptations that enable survival under extreme conditions (e.g., high pressure, temperature extremes, limited energy supply, existence with extremely slow growth, recalcitrant, and ancient organic matter supply) and are a potentially untapped resource for biotechnological applications. In addition, the potential response of the deep biosphere to anthropogenic activity, such as sequestration of carbon dioxide, fracking and the deep storage of spent nuclear fuels needs to be seriously considered. A range of abiological hydrogen generation ('dark energy') processes (radiolysis, mechanochemistry, serpentinization) have been considered to be important in supporting an anaerobic deep biosphere that would be completely independent of surface photosynthesis. Interestingly, some of these processes appear to be stimulated by microbial activity. This has implications for the origin of life, and potential life on other planets, even those with an inhospitable surface.

Defining Statement

Mycoplasma and *Ureaplasma* species are bacteria that lack a cell wall. These organisms evolved in close association with their eukaryotic hosts, resulting in an extreme genome reduction. In this article, the biology of the mollicutes is discussed with special emphasis on their pathogenic features, disease associations, cell and molecular biology.

Introduction

Mycoplasma and *Ureaplasma* are two important genera of the bacterial group called mollicutes. The name mollicutes – *soft skin* – reflects the major collective characteristic of these bacteria which is the lack of a cell wall, leaving the cells enclosed only by a trilaminar plasma membrane. This property distinguishes them from all other bacteria. In nature, mollicutes are never found as free-living organisms. Hosts are either animals including humans (*Mycoplasma*, *Ureaplasma*) or plants and insects (*Spiroplasma*, *Phytoplasma*) (Table 1). *Mycoplasma* species that infect humans usually cause respiratory diseases (*Mycoplasma pneumoniae*) or urogenital infections (*Mycoplasma genitalium*, *Mycoplasma hominis*, and *Ureaplasma* species), though many species exist in the respiratory or urogenital tracts as harmless commensals.

The close association of mollicutes with eukaryotic hosts and their adaptation to habitats with a good nutrient supply and relatively constant growth conditions led to a remarkable process of reductive genome evolution. The organism with the smallest known genome capable of independent life when provided with rich artificial medium is *M. genitalium*. This organism has a genome size of only 580 kbp and encodes about 480 proteins, as compared to about 4 million kbp and 4000 genes for bacteria such as *Escherichia coli*. These small genomes have made the mollicutes important tools for the new discipline of synthetic biology.

The Systematics of the Mollicutes

Evolution of Mollicutes

The analysis and comparison of 16S rRNA sequences revealed that the mollicutes have a distinct lineage from the Gram-positive bacteria with genomes of low GC content. It is believed that the first mollicutes emerged some 600 million years ago and that significant loss of ancestral genomic sequences was a major force in their evolution.

The mollicutes can be subdivided in several ways. Traditional classifications rely on their physiological and phenotypic properties, whereas more recent classification schemes are based on the similarity of their 16S rRNA (Figure 1) or conserved protein families. One conventional way of classifying the mollicutes is based on their requirement for sterols. Most genera need sterols for growth, whereas this is not the case for the members of the genera *Acholeplasma*, *Anaeroplasm*, and *Mesoplasma* (Table 1). However, this requirement can only be determined for those mollicutes that can be cultivated, and many representatives have not yet been cultured, including all species of the genus *Phytoplasma*. The mollicutes may also be classified according to whether they ferment glucose, utilize arginine, or hydrolyze urea. Another peculiarity of most mollicutes is that many species use the UGA codon to specify tryptophan rather than as a stop codon as in the universal genetic code. Only the genera *Acholeplasma* and *Phytoplasma* use UGA as a stop codon. Because this is the ancestral property, it can be assumed that *Acholeplasma* and *Phytoplasma* represent the more ancestral mollicutes. For practical reasons, the mollicutes are grouped in four orders that do not represent the phylogenetic relationships. An overview of these taxa is provided in Table 1. The two major genera of significance as human pathogens are *Mycoplasma* and *Ureaplasma*.

Genus *Mycoplasma*

The genus *Mycoplasma* is a paraphyletic collection of mollicutes that are widespread in nature as parasites of humans, mammals, birds, reptiles, and fish. It is the largest genus in the class Mollicutes and contains at least 118 species, 17 of which have humans as their primary host, though not all are considered pathogenic. Organisms in the genus *Mycoplasma* can be distinguished from the other mollicute genera because they are non-helical, require sterols, do not hydrolyze urea, are not obligate anaerobes, have optimum growth temperature of 37°C or higher, and have genomes of 580–1350 kbp.

The first representative of the genus *Mycoplasma* was identified in 1898 as the causative agent of contagious bovine pleuropneumonia (*Mycoplasma mycoides*). The human pathogens *M. hominis* and *M. pneumoniae* were discovered in 1937 and 1944, respectively.

This article is an update of J. Stülke, H. Eilers, S.R. Schmidl, *Mycoplasma* and *Spiroplasma*, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 208-219

Table 1 The systematic groups of the mollicutes

Order	Genus	Genome size	Sterols required	G + C content of DNA (mol%)	Characteristics	Habitat
Mycoplasmatales	<i>Mycoplasma</i> ^a (118 species)	580–1350 kb	Yes	23–40	Growth optimum: 37°	Humans, animals
	<i>Ureaplasma</i> ^b (7 species)	760–1140 kb	Yes	25–32	Urea hydrolysis	Humans, animals
Entomoplasmatales	<i>Entomoplasma</i> (6 species)	870–900 kb	Yes	27–34	Growth optimum: 30°C	Insects, plants
	<i>Mesoplasma</i> (11 species)	825–930 kb	No	26–32	Growth optimum: 30°	Insects, plants
	<i>Spiroplasma</i> (38 species)	780–2220 kb	Yes	24–31	Growth optimum: 30–37° Helical motile filaments	Insects, plants
Anaeroplasmatales	<i>Anaeroplasma</i> (4 species)	1500–1600 kb	Yes	29–33	Obligate anaerobes	Bovine/ovine rumen
	<i>Asteroleplasma</i> (1 species)	1500 kb	No	40	Obligate anaerobes	Bovine/ovine rumen
Acholeplasmatales	<i>Acholeplasma</i> (18 species)	1500–1650 kb	No	26–36	Growth optimum: 30–37°	Animals, plants, insects
	<i>Phytoplasma</i> ^c (35 species)	640–1185 kb	Not known	23–29	Uncultured <i>in vitro</i>	Insects, plants

^aThe total number includes subspecies.

^b*U. urealyticum* and *U. parvum*, formerly considered biovars of *U. urealyticum*, are now classified as two separate species.

^cPhytoplasmas are *Candidatus* species of mollicutes of plants and insects genetically related to the *Acholeplasmatales*.

**Figure 1** Phylogenetic grouping of the class *Mollicutes* based on 16S rRNA analyses of the type genera plus representatives of other major clusters.

Adapted from Bergey's Manual of Systemic Bacteriology, Phylum XVI. Tenereutes Murray 1984a, 356VP (Effective publication: Murray 1984b, 33.), Figure 105, by D.R. Brown, 2011 and reproduced with kind permission from Springer science and Business Media.

In 1981, *M. genitalium* was isolated from a patient suffering from nongonococcal urethritis. *Mycoplasma amphoriforme*, the most recently reported human mycoplasmal species, was first described in 2005. It has been recovered from the respiratory tracts of several persons with antibody deficiency and various types of chronic lung diseases, but its role as a primary pathogen of humans has not been well established.

The genus *Mycoplasma* now includes several *Candidatus* species of cell wall-less uncultivated parasitic bacteria based on 16S rRNA gene sequence analysis. Some of these organisms were previously classified as *Rickettsia* in the genera *Haemobartonella* and *Eperythrozoon*. Most mycoplasmas exhibit a rather strict host and tissue specificity, probably reflecting their highly specific metabolic demands and their parasitic lifestyle. For example, *M. pneumoniae* and *M. genitalium* are preferentially detected in the respiratory and urogenital tracts of humans, respectively.

The complete genome sequences of several species of the genus *Mycoplasma*, including all of the human pathogenic species, have been determined. This large interest in the variability of the *Mycoplasma* genetic complement is stimulated by the interest in creating artificial organisms based on the *Mycoplasma* species. The genome sequences revealed the reason for the complex nutritional requirements of the mycoplasmas: they lack the genes for many biosynthetic pathways and are thus dependent on their host or on the artificial medium to provide these required nutrients. Another interesting feature revealed by genome sequences is that very few

known regulatory proteins are present. Again, this is reflective of their close adaptation to one single natural habitat and a result of the reductive evolution. A metabolically versatile bacterium such as *Pseudomonas aeruginosa* that is capable of thriving in a wide variety of environments reserves as much as 10% of its genome for regulatory genes, but only a small number of these genes can be found in the mycoplasmas.

Genus *Ureaplasma*

Shepard provided the first description of T-strain mycoplasmas, eventually known as ureaplasmas in 1954 when he isolated them from men with urethritis. Originally, there was only a single species, *U. urealyticum*, named in 1974 and eventually shown to consist of at least 14 serovars. Eventually the species was divided into 2 biovars that have now been given separate species status. *U. parvum* includes serovars 1,3,6, and 14 while *U. urealyticum* includes the remaining serovars (2,4,5,7,8,9,10,11,12, and 13). There are at least 5 other *Ureaplasma* species that infect cats, dogs, cattle, or birds. This genus is unique among mollicutes in that the organisms have a unique and obligate requirement for urea from which they generate metabolic energy through urease enzymes. Their genomes range from 750–1140 kbp.

Cytology of the Mollicutes

The lack of a cell wall is caused by the absence of genes encoding enzymes for peptidoglycan biosynthesis and is closely linked to another characteristic feature of the mollicutes which is their cellular pleomorphism. Individual cells vary in shape from coccoid to flask-shaped cells or helical filaments, reflecting their flexible cytoskeleton. The mollicutes differ from other bacteria not only because they lack a cell wall but also by their small cell sizes. For example, a typical cell of *M. pneumoniae* is 1–2 μm long and 0.1–0.2 μm wide (Figure 2). In contrast, a typical rod-shaped bacterial cell (such as *E. coli*) is 1–4 μm in length and 0.5–1 μm in diameter. *M. pneumoniae* produces spherical colonies on SP4 agar that may be approximately 100 μm in diameter, whereas *M. hominis* produces characteristic fried egg colonies (Figure 3) and ureaplasmas form very small fried egg type colonies on agar of about 15–60 μm .

The absence of a cell wall has serious consequences for the osmotic stability of the mollicute cells. They are much more sensitive to changes of the osmotic conditions than bacteria possessing a cell wall. The parasitic lifestyle of the mollicutes may be directly related to their osmotic sensitivity. The hosts provide them with osmotically constant conditions that would not be found in the external environment. For example, *M. genitalium* is a parasite of the human urogenital tract, and its transmission by sexual contact ensures minimal exposure of the bacteria to an external, osmotically variable, environment.

Figure 2 Electron micrograph of a cell of *Mycoplasma pneumoniae*. The terminal organelle (also called the tip structure) is visible in the upper part of the cell. Scale bar = 200 nm.

Figure 3 Colonies of *Mycoplasma hominis* growing on A8 agar (126X). Colonies are typically 200–300 μm in diameter and are best visualized using a stereomicroscope. *M. hominis* demonstrates the typical fried egg appearance characteristic of many species in the genus. Adapted from *Mycoplasmas and Ureaplasmas as Neonatal Pathogens*, Figure 4, by K.B. Waites, B. Katz, and R.L. Schelonka, *Clinical Microbiology Reviews* 18:757–789, 2005. Reproduced with permission from ASM Press.

Some species such as *M. pneumoniae* and *M. genitalium* and *M. penetrans* have a flask- or clublike tip structure (Figure 2). This tip structure is a complex and specialized attachment organelle that has evolved to facilitate the parasitic existence of the mycoplasmas. The tip structure is made up of a network of adhesins, interactive proteins, and accessory proteins, which cooperate structurally and functionally to mobilize and concentrate adhesins at the tip of the cell. The major adhesin of *M. pneumoniae* is the 170 kDa P1 protein that is responsible for the interaction of the bacteria with the host cells. In addition, the tip structure is important for the internalization of intracellular mollicutes such as *M. genitalium*. This may protect the bacterial cells against the host immune system.

Mycoplasma species are able to glide on solid surfaces with the help of their terminal attachment organelle. Terminal organelles that are detached from the body of the *M. pneumoniae* cell are released by some mutants. These detached organelles are still capable of gliding, demonstrating that this organelle acts as a novel engine that allows cellular movement.

As other bacteria, the mollicutes divide by binary fission. Again, the terminal organelle seems to be very important for this process. Cell division in *M. pneumoniae* is preceded by the formation of a second tip structure adjacent to the existing one. The two terminal organelles then separate leading eventually to cytokinesis.

Biochemistry and Metabolism of the Mollicutes

The reductive evolution of the mollicutes is reflected in their limited metabolic properties and energy-yielding systems. Many common biosynthetic systems are partially or completely lacking and there are considerable differences among the various species. No quinones or cytochromes have been found in any representative. The electron transport system is flavin-terminated. Thus, ATP is produced by substrate-level phosphorylation, a less efficient mechanism as compared to oxidative phosphorylation.

Both *M. pneumoniae* and *M. genitalium* utilize glucose as their primary metabolic substrate; whereas *M. hominis* utilizes arginine and *Ureaplasma* spp. hydrolyze urea for generation of metabolic energy. Glycolytic kinases of some mollicute species have functions in addition to that in glycolysis. These enzymes can use not only ADP/ATP but also other nucleoside diphosphate/triphosphate couples. Thus, these enzymes (phosphofructokinase, phosphoglycerate kinase, pyruvate kinase, and acetate kinase) compensate for the lack of the normally essential *ndk* gene encoding nucleoside diphosphate kinase that is required for nucleotide biosynthesis. The complete set of genes encoding components of the Embden-Meyerhoff-Parnas glycolysis pathway is complete in *M. genitalium* and *M. pneumoniae*, which are able to generate ATP through glucose hydrolysis, but *M. hominis* lacks a single gene in the pathway.

Glycolysis is not the only source of ATP formation by substrate level phosphorylation in the mollicutes. Pyruvate can be oxidized to acetyl-CoA by pyruvate dehydrogenase. Acetyl-CoA can be further catabolized by phosphotransacetylase and acetate kinase in an additional substrate level phosphorylation resulting in the formation of acetate. An alternative pathway of pyruvate consumption is its reduction to lactate, leading to the regeneration of NAD^+ .

In addition to utilization of glucose, *M. pneumoniae* can utilize glycerol and fructose. Interestingly, arginine is not used even though the genetic equipment to utilize this substrate is present in the genome. In the case of *M. pneumoniae*, the enzyme is believed to be inactive due to a frameshift mutation leading to a premature stop in the *arcA* gene.

The arginine dihydrolase pathway can also be found in *M. hominis*. Arginine hydrolysis by this pathway results in the production of ornithine, ATP, CO_2 , and ammonia. The pathway uses three enzymes: arginine deiminase, ornithine carbamoyl transferase, and carbamate kinase. The degradation of arginine is coupled to equimolar generation of ATP by substrate-level phosphorylation.

Mollicutes possess very limited metabolic and biosynthetic activities for amino acids, carbohydrates, and lipids as compared to 'conventional' bacteria. *M. pneumoniae* scavenges nucleic acid precursors and does not synthesize purines or pyrimidines de novo. These may be provided by RNA and DNA that have been degraded by potent mycoplasmal nucleases. Furthermore, both

M. genitalium and *M. pneumoniae* lack all the genes involved in amino acid synthesis, making them totally dependent on the exogenous supply of amino acids from the host or from the artificial culture medium. The mycoplasmas have also lost most of the genes involved in cofactor biosynthesis; therefore, to cultivate them *in vitro*, the medium has to be supplemented with essentially all the vitamins.

Being dependent on the exogenous supply of many nutrients would predict that mycoplasmas need many transport systems. Surprisingly, *M. genitalium* and *M. pneumoniae* possess a only small number of transport proteins compared to the 281 transport and binding proteins annotated in *E. coli*. The apparent low substrate specificity of some of the mollicute transport systems, such as those for amino acids, may also contribute to the significant gene reduction observed.

Although mollicutes produce hydrogen peroxide, *M. pneumoniae* and *M. genitalium* lack the genes dealing with oxidative stress, such as those encoding catalase, peroxidase, and superoxide dismutase. A thioredoxin reductase system, identified in the mycoplasmas, may protect them from reactive oxygen compounds.

A major problem for the research with mollicutes is the difficulty of cultivating them *in vitro*. Only a minority of the mollicutes existing in nature have been cultivated so far. For example, none of the phytoplasmas infecting insects or plants has been cultivated *in vitro*. To overcome the metabolic deficiencies of the mycoplasmas, complex media are used for their cultivation. The media are usually based on beef heart infusion, peptone, yeast extract, and serum with various supplements. Serum has been shown to provide, among other nutrients, fatty acids and sterols that are required for membrane synthesis. For most mollicutes, ureaplasmas being a notable exception, the pH is adjusted to a slightly alkaline value, conditions that imitate those in the eukaryotic host.

Pathogenesis and Disease Associations

Pathogenicity has been most intensively studied with *M. pneumoniae*. This organism is a common cause of tracheobronchitis and community-acquired pneumonia in persons of all ages and is particularly prone to spreading in closed populations such as military camps, boarding schools, and prisons. Following inhalation, organisms are opsonized by complement or antibody, macrophages are activated and migrate to the site of infection and neutrophils, plasma cells, B and T lymphocytes infiltrate the lung. The organism attaches to ciliated respiratory epithelium using its specialized attachment organelle through a complex process involving numerous transmembrane as well as cytoskeletal proteins, including a 170-kDa P1 protein which is present over the entire membrane surface, but is concentrated in the attachment organelle. Numerous accessory proteins are also involved in cytoadherence, including HMW1, 2, and 3, and P90, P 40 and P30. Once the polar structure is established, an independently assembled complex of proteins B, C, and P1 complete formation of the organelle. The importance of P1 in cytoadherence is demonstrated by the fact that mutants lacking P1 are unable to adhere to cells and antibodies directed against P1 can block adherence. An ADP-ribosyl transferase, similar to pertussis toxin, known as the community-acquired respiratory distress syndrome (CARDS) toxin binds to surfactant protein A and enters the host cell by means of clathrin-mediated endocytosis. The toxin leads to ciliostasis and nuclear fragmentation and stimulates the production of proinflammatory cytokines and acute cellular inflammation, ultimately leading to airway damage. The amount of toxin produced correlates with disease severity. It has been suggested that cytokine production by the host response to *M. pneumoniae* infection may lead to chronic pulmonary diseases such as bronchial asthma.

Another major factor contributing to cytotoxicity and thus to pathogenicity of this mycoplasma is the formation of hydrogen peroxide. The hydrogen peroxide formed by *M. pneumoniae* acts in concert with endogenous toxic oxygen molecules generated by the host cells and induces oxidative stress in the respiratory epithelium. The effects of the peroxide on the host cells include loss of reduced glutathione, denaturation of hemoglobin, peroxidation of erythrocyte lipids, and eventually the lysis of the cells. Hydrogen peroxide also confers hemolytic activity. A nuclease produced by *M. pneumoniae* has the ability to enter host cells and induce apoptosis. Intracellular localization has been described in tissue culture models and if it occurs *in vivo*, may contribute to establishment of chronic infection by protecting the organisms from direct contact with cells of the host immune system, antibodies, and complement. Immunomodulation of the host immune response may occur through stimulation of B and T lymphocytes. Many of the clinical manifestations of mycoplasmal respiratory disease as well as extrapulmonary complications can be caused by autoimmune immunologic and inflammatory effects produced by the host in response to antigenic mimicry of eukaryotic structures by functional sites of microbial components, including the cytoadhesins. A strong humoral immune response typically results from a primary infection with *M. pneumoniae* in an immunocompetent host. Antibodies are directed against proteins and lipids, including the cytoadhesins. IgM can be detected after about one week, followed by IgG about 2 weeks later. IgM can sometimes persist for several weeks to months and may not be detectable in subsequent infections in middle aged or older adults who have had several previous infections. Surface antigen rearrangements may be responsible for host susceptibility to repeated infections over time.

Acquired antimicrobial resistance to macrolides through point mutations in 23S rRNA has become a major problem in *M. pneumoniae* over the past several years in Asia. Greater than 90% of clinical isolates from some regions of Japan and China are now highly-resistant to drugs such as erythromycin, clarithromycin, and azithromycin. Macrolide resistance is now being reported from Europe and North America, but rates are not nearly as high as those in Asia. Most of the reported resistance has involved children thus far, but adults may also be affected. Resistant organisms tend to cause more severe and prolonged illness that often necessitates substituting alternative antimicrobials such as fluoroquinolones or tetracyclines.

M. hominis is a common commensal organism in the lower urogenital tract of healthy persons and is often isolated in conjunction with *Ureaplasma* spp. Despite the frequency with which *M. hominis* is detected in healthy persons, it may cause

conditions such as pyelonephritis, pelvic inflammatory disease, post-partum endometritis, bacterial vaginosis, as well as systemic infections in newborn infants including congenital pneumonia and meningitis. Bacteremia, wound infections, and arthritis sometimes occur as systemic manifestations of *M. hominis* infections in adults, especially in persons with dysfunction in the humoral immune system. *M. hominis* does not have a prominent attachment tip, but it is able to adhere to various types of host cells. A complex of four cytoadhesive surface membrane proteins has been described in *M. hominis*. This complex includes lipoprotein P60 and P80, which has an uncleaved amino-terminal signal protein mediating membrane anchoring. The lipoprotein P50, known as the variable adherence-associated antigen (Vaa) displays high-frequency phase and size variation and may undergo antigenic variation and participate in evasion of the host immune response. An additional surface protein P100, known as OppA, the substrate-binding domain of the oligopeptide permease, is also involved in *M. hominis* cytoadherence and apoptosis. Release of NH_3 as a product of arginine hydrolysis has been suggested as a virulence factor of *M. hominis*, resulting in cytotoxic effects. Reports of hyperammonemia in immune suppressed persons with systemic infection with *M. hominis* provide support for this observation. Tetracycline resistance mediated by the *tetM* transposon occurs to a variable degree in *M. hominis*. Moreover, fluoroquinolone resistance caused by mutations in DNA gyrase and/or topoisomerase IV has also been reported.

M. genitalium is now known to be a significant cause of male urethritis as well as female cervicitis, and pelvic inflammatory disease. Whether it is an important pathogen affecting pregnancy outcome and neonates has not been established. In contrast to *M. hominis* and *Ureaplasma* spp., *M. genitalium* is less commonly detected in the lower urogenital tracts of healthy persons. The terminal structure of *M. genitalium* is composed of at least seven proteins, two of which, MgPa and P110 are necessary for cytoadherence, in association with other accessory proteins. The MgPa adhesin shows significant homology with P1 in *M. pneumoniae*, and like P1 is a strong immunogen. Another protein P32 involved in cytoadherence also has homology to an *M. pneumoniae* adhesin, P30. Following cytoadherence, *M. genitalium* can invade epithelial cells and localize in the nucleus.

Repetitive elements in the *M. genitalium* adhesin gene have strong sequence similarity to repetitive DNA elements in *M. pneumoniae*. Typical of other human mycoplasmal infections, antigenic variation of membrane proteins in *M. genitalium* encoded by *mgpB* and *mgpC* in the MgPa operon due to recombination and slipped-strand mispairing with nine partial non-coding MgPa loci is believed to facilitate chronic infection. A calcium-dependent membrane-associated nuclease MG186 enables the organism to degrade host nucleic acid, thus providing a source of nucleotide precursors for its own replication. Of major concern is the acquisition of genes that mediate macrolide and sometimes fluoroquinolone resistance by *M. genitalium*, making infections with this organism difficult to treat. Most data concerning acquired antimicrobial resistance are based on small numbers of cases, so the extent to which it occurs is not known, but it is apparently due to selective antibiotic pressure in treatment of sexually transmitted infections. For many years, cross reactivity in the complement fixation serological tests between *M. pneumoniae* and *M. genitalium* caused diagnostic confusion because of their antigenic similarities. This became less important when other more specific serological methods such as enzyme immunoassays became more widely used.

M. fermentans received considerable attention several years ago when it was thought possibly to play a role as a mediator or cofactor in development of AIDS, as a cause of Gulf War Syndrome, and Chronic Fatigue Syndrome. Subsequent studies however, have failed to prove these disease associations and now it is appreciated that this mycoplasma behaves as an opportunistic pathogen causing systemic infections in persons with HIV, as well as those who are HIV-negative. *M. fermentans* has been recovered from the throats of children with pneumonia and from adults with influenza-like illnesses. There is no evidence that *M. fermentans* causes urethritis or cervicitis, but it has been detected by PCR in placentas with chorioamnionitis, suggesting venereal transmission is possible. This mycoplasma has also been isolated from the joints in persons with inflammatory arthritis, and there has been speculation that it may be involved in rheumatoid arthritis, though this has not been conclusively proven. *M. fermentans* lacks a well-defined attachment organelle, but it is still able to invade host cells. Glycoglycerol lipid (GGPL-III) and lipoprotein P29 are believed to be responsible for *M. fermentans* cytoadherence to host cells as well as for triggering an inflammatory response. Understanding the role of *M. fermentans* as a possible opportunistic pathogen in humans is complicated because it is known to colonize mucosal surfaces in some healthy persons, as is the case with *M. hominis* and *Ureaplasma* spp.

Ureaplasmas may be isolated from the lower urogenital tract in as many as 80% of healthy adult women and may also be detected in the urethras of a significant proportion of healthy men. Ureaplasmas are readily transmitted vertically in utero or at time of delivery. Most studies have reported that *U. parvum* is more common as a colonizer than *U. urealyticum*. As is the case with other mollicutes, ureaplasmas reside primarily on mucosal surfaces with preference for the urogenital tracts of adults and respiratory tracts in neonates who acquire the organisms from their mothers *in utero* or at delivery. A number of clinically significant illnesses have been attributed to ureaplasmas, despite their common occurrence in healthy persons. These include urethritis, urinary calculi, postpartum endometritis, and chorioamnionitis, and preterm labor, in adults and bacteremia, meningitis, abscesses, congenital pneumonia, and chronic lung disease in infants, mainly affecting those born preterm. Systemic spread to the bloodstream, central nervous system, joints and other body sites rarely occurs outside of the neonatal period except in persons with defects in the humoral immune system.

Infection with ureaplasmas produces a robust inflammatory response in conditions such as chorioamnionitis. Inflammation is enhanced by upregulation of pro-inflammatory cytokines such as tumor necrosis alpha and interleukin-8. Although no toxins have been detected in ureaplasmas to date, they can adhere to erythrocytes, spermatozoa, neutrophils, and urethral epithelial cells. Their adhesins are surface proteins for which the receptors may be sialyl residues and/or sulfated compounds, similar to what have been described for *M. pneumoniae* and other mycoplasmas. Some experimental data suggest the presence of several ureaplasma adhesins, some of which are species- or serovar-specific and antigenic. The 96 kDa surface-expressed antigen may be one such adhesin. Surface antigen variation may be a means for persistence and repeated infections with these organisms. Another means by which

ureaplasmas may evade the host immune response to produce chronic infections may involve suppression of endogenous antimicrobial peptides that are an integral part of the innate host immune response by downregulation of expression of their respective genes. Ureaplasmas can produce IgA protease and hemolysins that are believed to be encoded by *hlyC* and *HlyA*. Ureaplasmas release NH_3 through urea hydrolysis mediated by ureases and this is the mechanism by which these organisms produce struvite urinary stones and hyperammonemia that has been reported in lung transplant recipients. At least 15 potential nucleases have been identified in *Ureaplasma* genomes. Acquired antimicrobial resistance has been described in both *Ureaplasma* spp. for macrolides, fluoroquinolones, and tetracyclines. Depending on the population tested and the history of antibiotic exposure, resistance to tetracycline may be fairly common, affecting as many as half of all isolates, mediated by the *tetM* transposon. Mutations affecting activities of DNA gyrase and/or topoisomerase IV mediating resistance to fluoroquinolones and mutations in 23S rRNA affecting susceptibility to macrolides appear to be uncommon, affecting less than 5% of clinical isolates of *Ureaplasma* species in the southeastern United States.

Since the very first descriptions of *Ureaplasma* serovars and designation of the two biovars as individual species, there has been much speculation regarding whether there was differential pathogenicity at the serovar or species level. Evidence available to date supports the concept that *U. urealyticum* is more pathogenic than *U. parvum* in male urethritis, but data are much less convincing for other conditions. There is no credible evidence that differential pathogenicity exists at the serovar level, primarily because of extensive horizontal gene transfer among the 14 known serovars that are divided between the two species.

Various commensal mycoplasmal species of the respiratory and urogenital tracts of humans can occasionally be detected as causes of systemic infections, usually in immunosuppressed hosts with antibody deficiencies, as can mycoplasmal species that normally infect animals. These uncommon occurrences underscore the importance of a functional humoral immune system in protection against serious mollicute infections.

Genetics of the Mollicutes

Gene Expression

The basic mechanisms of gene expression have not been studied extensively in the mollicutes. These organisms possess a conventional bacterial RNA polymerase, but unlike most other bacteria, they encode only one sigma factor of the RNA polymerase. Thus, diversity of promoters and RNA polymerase holoenzymes are not used for regulatory purposes in the mollicutes. The transcription start sites have been identified for several *M. pneumoniae* genes, and it turned out that the -10 region of these promoters is similar to that recognized by the housekeeping sigma factors of other bacteria such as *E. coli*. In contrast, there is no conserved -35 region. These observations were confirmed by an analysis of the sequence determinants that are required for promoter activity in front of the *M. pneumoniae* *ldh* gene encoding lactate dehydrogenase. The -10 region is essential for transcription initiation, whereas the -35 region could be mutated without any consequences. Thus, the single *M. pneumoniae* RNA polymerase holoenzyme recognizes only the -10 region for promoter recognition.

Another peculiarity of the *M. pneumoniae* transcription machinery is the lack of the termination factor Rho, and correspondingly, the absence of Rho-dependent transcription terminators. Surprisingly, a bioinformatic analysis of bacterial genomes and the free energy values of RNAs around the end of open reading frames suggest that the mollicutes also do not contain functional Rho-independent transcription terminators. This raises the important question of how transcription is terminated in the mollicutes or whether it is terminated at all. The answer came from Northern blot experiments aimed at the identification of *in vivo* transcripts, and this answer is ambiguous. Indeed, defined transcripts were observed in a few cases, such as the *M. genitalium* and *M. pneumoniae* *ftsZ* gene clusters or the *M. pneumoniae* *ptsH* gene. The existence of these defined transcripts implies that there are also defined transcription terminators present. However, these terminators may be very rare. This might explain the observation that unrelated genes are expressed as parts of one transcription unit in the mollicutes. Moreover, most attempts to determine transcript sizes by Northern blot analysis in the mollicutes have failed. This is probably the result of mRNA length polymorphisms, which prevent the detection of clearly defined RNA species.

Intrinsically fluorescent proteins such as the green fluorescent protein (GFP), the yellow fluorescent protein (YFP) and their derivatives have been used to study protein localization, interactions, cell division and gene expression. These proteins have been used in *M. pneumoniae* to demonstrate the subcellular localization of the proteins HMW2, P65, P41, and P24 and to confirm them as components of the attachment organelle. Moreover, P41 and P24 appeared to be cytoskeletal proteins.

Most genes in the mollicutes have the same orientation on the chromosome and the intergenic regions are usually quite short, when present. The transcription of most of these large gene clusters is colinear with replication. This genome organization also favors polycistronic transcription of large gene clusters.

The lack of defined mRNA species results not only from the absence of transcription terminators, but also from the weak conservation of sequences that mediate transcription initiation. Indeed, the -10 regions predicted from the analysis of many start points occur about 2900 times in the 816 kbp genome of *M. pneumoniae*. This large number of possible transcription initiation sites is also reflected by the observation of substantial antisense transcription in both *M. genitalium* and *M. pneumoniae*.

M. pneumoniae contains 8 known transcription regulators. The low number of transcription factors in the mollicutes and the weak stringency of transcription signals might therefore reflect their close adaptation to specific habitats that provide a good supply of nutrients and protect the bacteria from harmful environmental conditions. Moreover, the good supply of nutrients from the host may abolish the need for transcription regulation, thereby switching off the expression of genes if their products are not required.

Translation is one of the most prominent activities of the mollicute cell. As much as 15% of the genome of the mollicutes is devoted to translation-related functions. The principal mechanisms of translation in the mollicutes are identical to those found in other bacteria. Because of the low genomic GC content, the codon usage is strongly biased toward AT-rich codons. The molecular mechanisms of translation initiation in *M. pneumoniae* and its close relatives still await elucidation.

Posttranslational Protein Modification

Post-translational protein modification plays an important role in protein secretion. Several types of protein modifications have been described which include (1) cleavage of signal peptides; (2) acetylation; (3) endoproteolytic cleavage of secreted proteins; and (4) phosphorylation. Much of the existing information about protein modification in mollicutes pertains to *M. pneumoniae*. Among 693 predicted open reading frames in the *M. pneumoniae* genome, 620 have been identified by proteome studies and functions for about 70% of the proteome have been assigned thus far. Mpn 142 is one of 3 genes in the operon that includes the P1 adhesin (Mpn 141) and Mpn 140. Mpn 142 undergoes endoproteolytic cleavage to generate the amino terminal 40-kDa P40 and the carboxy terminal 90-kDa P90 proteins that reside on the cell surface and complex with P1 and other proteins in the terminal organelle. There is also evidence that *M. pneumoniae* has signal peptidase activity and that lipoprotein families are also subject to endoproteolytic cleavage. Many cleavage fragments remain surface bound in the mycoplasmal cell membrane. Additionally, proteins associated with glycolysis, components of translational machinery, and adhesins can be phosphorylated and/or lysine acetylated. Such modifications alter the cellular proteome and influence protein interaction pathways.

Considerable work has been devoted to the biochemical characterization of the protein kinase HPrK from *M. pneumoniae*. As in related proteins, it contains an essential Walker A motif for ATP binding. Mutations in this region severely affect both the kinase and the phosphatase activities of the protein. Fluorescence studies revealed that the *M. pneumoniae* HPrK has a significantly higher affinity for ATP than any other HPrK studied so far. This may explain why it is active even at low ATP concentrations. The *M. pneumoniae* HPrK was crystallized and its structure determined. As observed for homologous proteins, it forms a hexamer with the C-terminal domains in the active center.

An analysis of the *M. genitalium* proteome revealed that each identified protein is present at an average of 1.22 spots on a 2-D gel, suggesting posttranslational modification of about 25% of all proteins. Given the importance of protein phosphorylation in all other living organisms, it seems safe to assume that a large portion of these modified proteins is actually phosphorylated. A phosphoproteome analysis of *M. genitalium* and *M. pneumoniae* identified 5 and 3% of the total protein complement of these bacteria, respectively, as phosphoproteins. Among these proteins are not only enzymes of central carbon metabolism such as enolase and pyruvate dehydrogenase subunits, but also several cytoskeleton and cytodherence proteins.

Genomic Comparisons in the Mollicutes

One scientific question that has been of interest to humans is the problem of what constitutes life. Only today, in the era of genomics research, are we able to attempt an answer to this question. A major milestone in defining life was the identification of key features that characterize all living things. Among these features are metabolism, autonomous replication, communication, and evolution. With the availability of genome sequences, it is has become possible to determine the genetic equipment required for independent life. The mollicutes are of special interest in this respect because they have the smallest genomes that allow independent life under laboratory conditions.

Genome research with the mollicutes was begun in the 1990s and has been driven by two major challenges: (1) the identification of the minimal set of genes that is required for independent life and (2) the creation of artificial organisms that are based on this minimal gene set. The simplicity of the mollicutes and the broad body of knowledge on their biology makes them ideal starting points for these research areas.

Several different strategies have been applied to identify the minimal gene set required for life. The simplest approach is based on the comparison of sequenced genomes of different organisms. It seems safe to assume that those genes that are conserved in different organisms are more important than those that appear only in certain species. The smallest genome of any independent living organism known so far is that of *M. genitalium*. This bacterium has a genome of 580 kbp with 482 protein-coding genes. *M. pneumoniae* has a genome of 816 kbp with 779 genes coding for proteins. A comparison of the two genomes based on the initial descriptions of *M. genitalium* G37 (ATCC 33530) and *M. pneumoniae* M129 (ATCC 29342) reveals an overlap of 477 genes common to both species. This suggests that *M. pneumoniae* is an 'extended version' of *M. genitalium*. It is tempting to speculate that *M. genitalium* is further advanced on the pathway of reductive genome evolution. Indeed, some genes present in *M. pneumoniae* but not in *M. genitalium* such as the mannitol utilization genes are known to be nonfunctional in the former organism. Thus, *M. genitalium* seems to be very close to a true minimal organism.

Evaluations of 15 *M. pneumoniae* genomes at the University of Alabama at Birmingham by Next-Generation Sequencing using the Illumina MiSeq platform, that included previously sequenced strains M129 (ATCC 29342) and FH (ATCC 15531) demonstrated that greater than 99% sequence identity, despite the facts that the strains were collected over a span covering 1944 to 2009 from the United States, Europe, and Asia, and including both of the major subtypes, P1 and P2. The CARDS toxin gene had very little variation among the 15 strains, with only a single nucleotide polymorphism distinguishing P1 and P2 subtypes. Evidence for

horizontal gene transfer was minimal. The major region of variability was within the P1 and open reading frame 6 genes associated with the adhesin complex.

Only *M. hominis* type strain PG 21 (ATCC 23114) has been sequenced and reported, demonstrating it to be the second smallest human mollicute with a total of 665 kbp and 537 coding sequences. Comparative analyses indicated the occurrence of horizontal gene transfer between *M. hominis* and *U. parvum*, serovar 3 which had been sequenced earlier. This is not unexpected since these species occupy the same urogenital niche in humans. Despite many common genes, the pathogenic *Mycoplasma* species, *M. pneumoniae*, *M. genitalium*, and *M. hominis*, have distinct energy-generating pathways as well as different cytoadherence and virulence genes. Interestingly, when genomes of the urogenital species *M. hominis*, *M. genitalium*, and *U. parvum* were compared, there were 220 genes specific for *M. hominis*, 172 specific for *M. genitalium*, and 280 specific for *U. parvum*. Thus, only a subset of their genes is part of a common gene pool.

Additional recent studies have undertaken to compare the genomes of 19 *U. urealyticum* and *U. parvum* strains, including all 14 known serovars and several clinical isolates. *U. parvum* genomes had about 750–780 kbp with an average of 608 genes, of which 201 encode hypothetical proteins, while *U. urealyticum* genomes had 840–950 kbp with an average of 664 genes, of which 230 encode hypothetical proteins. The ureaplasma pangenome has 1010 protein coding genes of which 758 have orthologs in at least one other strain and 515 genes are universally conserved among all 19 strains, thereby comprising the ureaplasma core genome. The number of genes found on only a single serovar was 262. Despite the fact that IgA protease activity has been demonstrated in several *Ureaplasma* serovars, the presence of the gene encoding this enzyme could not be identified in any of the genomes. Thus, it is possible that the gene may be there but was not recognized as such in the computational genome analysis.

Some very interesting findings evolved from comparative analyses of *Ureaplasma* spp. genomes involving the multiple banded antigens (MBA) which are immunogenic and initially provided the basis for which the 14 serovars were established. Genomic analysis showed the *mba* genes to be part of a large complex superfamily which is phase variable with some serovars having identical sets of *mba* genes. These studies further support the concept that horizontal gene transfer occurs, especially with the more pathogenic *U. urealyticum*, and the organisms exist as quasi-species rather than being comprised of stable serovars.

A major achievement in genomics research in recent years was the chemical synthesis and assembly of the *M. genitalium* chromosome. Thus, an artificial chromosome can be synthesized and this DNA can be introduced into a living cell to provide the environment for the expression of this genome. This achievement has led to the replacement of one genome by another, a process called genome transplantation, which was demonstrated in mollicutes when a *Mycoplasma mycoides* genome cloned in *Saccharomyces cerevisiae* was transplanted into *Mycoplasma capricolum* recipient cells. These species were chosen as opposed to *M. genitalium*, which has the smallest genome, because of its extremely slow growth and difficult cultivation *in vitro*.

Molecular Biology and Genetic Tools

The detailed genetic analysis of the mollicutes has been hampered by the lack of genetic tools that allow the efficient expression of mollicute genes in heterologous hosts for purification and subsequent biochemical analysis, the stable introduction of foreign genetic material into a mollicute cell, and either the targeted construction or the targeted isolation of desired mutant strains. During the past few years considerable progress has been made in the field of mollicute genetics, making these organisms more accessible for genetic studies.

The occurrence of UGA codons in the genes of mollicutes has often prevented their expression in heterologous hosts for detailed biochemical analysis because they serve as stop codons in *E. coli* and other expression hosts. To circumvent this problem, a variety of different strategies had been employed, including the expression of UGA-containing genes in opal suppressor strains of *E. coli* that also read UGA as a tryptophan codon. As long as only few UGA codons are present in a gene, their sequential replacement by standard site-directed mutagenesis strategies might also be taken into consideration. However, the latter approach is time-consuming and cost-intensive with an increasing number of UGA codons. Recently, a strategy referred to as multiple mutation reaction (MMR) allowing the simultaneous replacement of multiple UGA codons in a single-step reaction was developed. This strategy is based on the use of 5'-phosphorylated oligonucleotides containing the desired mutations in a polymerase chain reaction (PCR). During the elongation steps, the external amplification primers are extended. As the mutation primers are designed to hybridize more strongly to their targets, the elongated amplification primers can then be ligated to the 5' ends of the mutation primer by a thermostable DNA ligase, yielding a DNA strand that contains the desired mutation. With this strategy, the simultaneous introduction of up to nine mutations in one single step is possible.

In combination with smart screening systems, transposons have been used for the disruption of genes but also as carriers for the introduction of genetic material into the chromosome. The transposons Tn916 and Tn4001 and their improved derivatives can be used in mollicutes. These transposons were originally isolated from *Enterococcus faecalis* and *Staphylococcus aureus*, respectively, and have a broad host range. Tn916 is a conjugative 18 kb transposable element that contains the *xis-Tn/int-Tn* genes for excision/integration, followed by the *tetM* tetracycline resistance determinant and a set of genes (*tra*) required for intercellular transfer. Tn916 does not generate target duplications at its integration site, because it transposes by an excision/integration mechanism that is based on staggered nicks in the donor DNA. Tn4001 is a 4.5 kb composite transposon consisting of two identical IS256 elements flanking the gentamicin/kanamycin/tobramycin resistance conferring *aac-aphD* gene. Tn4001 has been used for transforming several

Mycoplasma species. To increase the stability of transposon insertion mutants, mini-transposons on the basis of Tn4001 were constructed that have the transposase gene outside the transposable elements to prevent reexcision of the transposon after the first transposition event.

Targeted construction of gene knockout mutants via homologous recombination has been reported in a few mollicutes such as *M. genitalium*, *Mycoplasma gallisepticum*, *Mycoplasma pulmonis*, and *Acholeplasma laidlawii* to enable some investigation of the role of individual genes in pathogenesis. In the absence of homologous recombination, the only remaining way to obtain gene knockouts is transposon mutagenesis. Because of the randomness of integration, the screening of large transposon mutant libraries for the loss or gain of a specific phenotype is required to isolate a gene knockout of interest. If no screenable phenotype can be expected to be associated with a gene of interest, the only known feature of the desired gene knockout is the specific DNA junction between the gene of interest and the transposon. Based on this idea, a strategy referred to as 'haystack mutagenesis' has been designed that allows the targeted isolation of any viable transposon insertion strain out of an ordered library of transposon mutants. The concept of haystack mutagenesis is based on a saturating transposon mutagenesis to ensure that each dispensable gene is disrupted at a desired confidence level. Once the required number of transposon mutants has been isolated, they are arranged in pools of a reasonable size. These pools can then be screened by PCR using a gene-specific oligonucleotide and another one specific to the transposon for identifying the pool that contains the desired insertion. Subsequently, a similar screen at the level of the individual clones of the positive pool will identify the mutant of interest. This strategy has already been used for the isolation of several *M. pneumoniae* mutants. Alternatively, transposon mutant libraries can be screened for mutants that exhibit an interesting phenotype, such as loss of gliding motility.

There is ample evidence for transposon delivery into *Ureaplasma* genomes in nature through the acquisition of tetracycline resistance mediated by the *tetM* transposon. Despite several failed attempts, transposon mutagenesis has now been used successfully to transform 3 serovars of *U. parvum* and a clinical strain of *U. urealyticum* with a Tn4001-based mini-transposon plasmid containing a gentamicin-resistance selection marker, leading to random disruption of genes and phenotypic changes in the organism. This finding suggests that it may be possible to determine non-essential genes, deliver and express exogenous genes, and identify key pathogenic markers in human ureaplasmas.

Laboratory Detection

Culture is useful for *M. hominis* and *Ureaplasma* spp. since they grow rapidly from clinical specimens inoculated into appropriate liquid and solid media such as 10B broth and A8 agar, usually forming colonies that can be visualized under a stereomicroscope within 1 to 3 days. Ureaplasmas can be identified to genus level by tiny granular brown fried-egg colonies 15–60 µm in diameter on A8 agar. Rapidly growing mycoplasma species from urogenital specimens that produce larger fried egg type colonies on agar within 2 to 3 days can be identified to species level using PCR or alternative methods. However, *M. pneumoniae* and *M. genitalium* are quite fastidious and grow much more slowly. Culture of *M. genitalium* requires up several weeks, is rarely successful and need not be attempted. Serology is sometimes used for diagnosis of acute *M. pneumoniae* infections, but suffers from poor sensitivity and requires testing acute and convalescent sera for IgM and IgG for optimum results. Serology is not standardized, nor is it useful for detection of infections caused by any of the genital mycoplasmal species or ureaplasmas. For these reasons, molecular-based assays such as the PCR reaction are the most common means for rapid detection of *M. pneumoniae* and *M. genitalium*. PCR is also a suitable alternative for detection of *M. hominis* and *Ureaplasma* spp., but is generally more expensive than culture and less widely available due to the lack of commercialized assays in the United States. Other types of molecular-based assays used for detection of the various mycoplasma species have included loop-mediated isothermal amplification (LAMP), nucleic acid sequenced-based amplification (NASBA), and transcription-mediated amplification (TMA). Molecular-based assays are available through many reference laboratories for detection of *M. pneumoniae*, *M. hominis*, *M. genitalium*, *U. parvum*, and *U. urealyticum*, although no assays are commercially sold in the United States except for *M. pneumoniae*. Real-time PCR has improved specificity compared to conventional PCR, partly because of the use of probes labeled with a fluorophore and a quencher designed to correspond to a sequence located between the forward and reverse primers. Labeled probes allow a signal to be detected only if the probe has annealed to its complementary target sequence, thus minimizing cross-reaction and detection of undesired amplicons. Another aspect of real-time PCR that contributes to its specificity is that amplicon melting temperature is determined at the end of the assay and can be used to verify whether the desired PCR product is being detected. A variety of gene targets have been employed for detection of the various pathogenic mycoplasmas and ureaplasmas of humans using real-time PCR. In our laboratory, the non-coding sequence *repMp1* has been a useful target for real-time PCR assays for *M. pneumoniae* since it is present in multiple copies for improved sensitivity. For *M. genitalium*, *gap*, encoding glyceraldehyde-3-phosphate dehydrogenase overcomes problems encountered with 16S rRNA and *MgPa* targets. Several different genes have been described as targets for real-time PCR for *M. hominis*, including 16S rRNA, *gap*, *fstY*, *yidC*, and *tuf*, but the presence of mutations and sequence variations have caused problems with analytical sensitivity. Our laboratory has developed and validated a multiplex real-time PCR assay for detection and speciation of ureaplasmas based on two genes. *UU063* encodes a conserved hypothetical protein identical in all 4 *U. parvum* serovars that is absent in *U. urealyticum*. *UU10-0680* is an open reading frame that is conserved in all 10 *U. urealyticum* serovars, but absent in *U. parvum*. These assays perform very well and have an improved analytical and clinical sensitivity over quantitative culture.

Glossary

Biofilm A layer of adhesive exopolymeric substances attached to a surface and secreted by microorganisms forming colonies on it.

Bioleaching Refers to the microbial conversion of an insoluble metal (usually a metal sulfide or oxide) into a soluble form (metal sulfate).

Biomining The use of microorganisms to recover metals in industrial operations.

Bioremediation Use of microorganisms to remove toxic chemicals from the environment.

Biosorption Refers to the binding of metal ions by whole biomass (living or dead).

Chemolithoautotroph A microorganism that fixes CO₂ and obtains its energy by the oxidation of inorganic compounds.

Consortium A group of microorganisms living together and in which each individual benefits from the others.

Genome The complete set of genes present in an organism.

Genomics Refers to mapping, sequencing, and analyzing genomes.

Proteome The total complement of proteins present in a cell at any one time.

Proteomics Genome-wide study of the structure, function, and regulation of proteins in the cell.

Systems microbiology Considers microorganisms or microbial communities as a whole to create an integrated picture of how a microbial cell or community operates.

TEM	Transmission electron microscopy

Defining Statement

Microorganisms interact with heavy metals, transforming them by uptake, bioaccumulation, bioprecipitation, bioreduction, biooxidation and other mechanisms. Some of these activities result in the solubilization or extraction of metals which are successfully used in industrial biomining processes to recover valuable metals or in biorremediation to remove toxic metals from contaminated soils.

Microbial Transformations of Metals

Microorganisms interact with metals by several mechanisms, most of which are shown in Fig. 1. All bacteria require several metals that are essential for their functioning and the uptake of most of them is metabolism- or energy-dependent. For this bioaccumulation, they possess specific or general energy-dependent metal transporters to directly incorporate them or through chelation by means of organic compounds such as siderophores in the case of iron. Some of these transporters are used to bioaccumulate metals

[☆]Change History: June 2017. CA Jerez added new references and updated the sections and text in this article.

inside the cell. This can be done by sequestering the metal by proteins rich in cysteine or histidines or they can be chelated by inorganic polyphosphates (polyP), which are long chains of phosphate molecules joined through phosphodiester bonds and are highly negatively charged at neutral pH. Microorganisms such as *Acinetobacter* spp. bioprecipitate metals in the form of metal phosphates via hydrolysis of stored polyP depending upon alternating aerobic (polyP synthesis) and anaerobic (polyP hydrolysis and phosphate release) periods.

The metabolism-independent sorption of heavy metals or biosorption refers to the binding of metal ions by whole biomass (living or dead). It can take place by adsorption in which metals accumulate at the surface of the biomass and by absorption or a rather uniform penetration of the metal ions from a solution to another phase. Biomolecules present in the biomass contain several chemical groups that act as ligands (L²⁻ in Fig. 1) for the biosorption of the metal ions. The most common are the amino, carboxyl, phosphate, and sulfhydryl groups present in proteins, nucleic acids, and polysaccharides.

Microorganisms can also catalyze several biotransformations. They transform most toxic metals into less soluble or less volatile forms. One example is the reduction of metals such as Cr(vi) to Cr(iii), U(vi) to U(iv), Te (vi) to Te(0) and many others that results in the precipitation of the metal under physiological conditions. Another very well-studied biotransformation of a toxic metal is the bioreduction of Hg(ii) to the relatively nontoxic volatile elemental Hg(0).

Microorganisms also precipitate metals in the form of carbonates, hydroxides, or insoluble sulfides and phosphates. This constitutes a biomineralization, and due to the very low solubility products of these compounds formed, most of the soluble metals would be removed by precipitation in their liquid medium (Fig. 1).

Microorganisms That Solubilize Metals

A basic prerequisite for life is the existence of a chemical redox gradient to convert energy. This allows energy flow and its use in the biochemical reactions of the cells. Most cells use organic compounds like sugars as fuels (electron donors). Their oxidation in the

presence of oxygen or respiration provides carbon to the cell generating as end products CO_2 and H_2O and energy in the form of electrons. This energy is stored mainly in the form of ATP to be used in the cell metabolism. A group of special microorganisms (Bacteria and Archaea) known as chemolithoautotrophs are capable of using minerals as fuels. Their oxidation generates electrons to obtain ATP and the carbon is obtained by fixing CO_2 from the air. During this aerobic mineral oxidation metals are solubilized or bioleached.

Anaerobic respiration can also solubilize metals. In this case, the mineral acts as an electron acceptor and the metal is solubilized under reducing conditions. Several microorganisms are capable of reducing heavy metals and couple this reduction with the oxidation of energy sources such as hydrogen or organic compounds (formate, lactate, amino acids, and others). Characteristic examples are the reduction of Fe and Mn, which account for good part of organic carbon turnover in several environments (Lovley, 2000). Several of the dissimilatory metal-reducing bacteria not only reduce Fe and Mn but also other metals such as the toxic Cr(vi) and U(vi) and, therefore, microorganisms like *Shewanella oneidensis* could also be used for bioremediation.

The reactions just mentioned are part of normal biogeochemical processes in nature. They are performed under neutral conditions or as the majority of microorganisms do, at very high acidic values (pH 1–3 usually). This article will concentrate mainly on reviewing metals mobilization by acidophilic microorganisms.

Some of the general oxidation reactions that acidophiles are able to catalyze are given below.

These reactions not only solubilize the metals present in the minerals but also generate sulfuric acid. The acidophilic microorganisms, therefore, are able to stand not only low pH values but also very high metal concentrations. They possess heavy metal resistance or detoxification mechanisms. Neutrophilic bacteria have metal resistance mechanisms involving either an active efflux or a detoxification of metal ions by different transformations (Fig. 1). In the case of copper, for example, these include intracellular complexation, decreased accumulation, extracellular complexation, or sequestration in the periplasm. Neutrophilic bacteria are able to grow in a range of copper concentration between 1 and 8 mmol L^{-1} depending on the species. However, acidophiles such as *Acidithiobacillus ferrooxidans* or archaeons such as *Sulfolobus metallicus* can resist concentrations of copper up to 800 and 200 mmol L^{-1} , respectively (Orell et al., 2010). Most likely, they possess additional mechanisms to those present in neutrophiles, allowing them to have such dramatic metal resistance. It has been proposed that in microorganisms possessing large amounts of polyP, such as some chemolithoautotrophic acidophilic bacteria and archaea, these polymers may be actively involved in the elimination of toxic heavy metals such as Cu. This detoxification would take place through the enzymatic hydrolysis of polyP that would generate free phosphate that would bind the excess of cytoplasmic metal to form a metal–phosphate complex that is transported outside the cell through phosphate transporters (Fig. 1). These properties make these microorganisms very appropriate for their use in biomining and also for the bioremediation or removal of heavy metals from polluted places (see below).

Microbial Extraction of Metals From Ores and Biomining

The microbial solubilization of metals is widely and successfully used in industrial processes called bioleaching of ores or biomining, to extract metals such as copper, gold, uranium, and others (Brierley and Brierley, 2013). This process is done by using chemolithoautotrophic microorganisms. There is a great variety of microorganisms capable of growth in situations that simulate biomining commercial operations and many different species of microorganisms are living at acid mine drainage (AMD) sites (Hedrich and Schippers, 2016). The most studied leaching bacteria are from the genus *Acidithiobacillus*. *A. ferrooxidans* (Fig. 2(a)) and *Acidithiobacillus thiooxidans* are acidophilic mesophiles and together with the moderate thermophile *Acidithiobacillus caldus*, they belong to the Gram-negative γ -proteobacteria. Fig. 2(c) shows *A. ferrooxidans* cells growing in the form of a biofilm on the surface of an elemental sulfur particle, most likely as a monolayer. When this biofilm is removed from the solid particle by using a detergent (Fig. 2(d)), only those cells attached more strongly to the sulfur particle are remaining. They are seen as attacking the sulfur surface through a ‘pitting’ in which some cells are still tightly bound to the cavities and others have been released, leaving empty cavities. A similar attack has been observed on the surface of other minerals such as pyrite.

Members of the genus *Leptospirillum* are other important biomining bacteria that belong to a new bacterial division. Some Gram-positive bioleaching bacteria belonging to the genera *Acidimicrobium*, *Ferromicrobium*, and *Sulfobacillus* have also been described. Biomining using extremely thermophilic archaeons capable of oxidizing sulfur and iron (ii) has been known for many years, and the archaeons are mainly from the genera *Sulfolobus* (Fig. 2(b)), *Acidianus*, *Metallosphaera*, and *Sulfurisphaera*. Also some mesophilic iron (ii)-oxidizing archaeons belonging to the *Thermoplasmatales* have been isolated and described – *Ferroplasma acidiphilum* and *Ferroplasma acidarmanus*. In fact, a consortium of different microorganisms participates in the oxidative reactions, resulting in the

Fig. 2 Some examples of acidophilic microorganisms that participate in metal extraction through biomining. (a) *Acidithiobacillus ferrooxidans* cells. (b) A group of *Sulfolobus metallicus* cells. (c) A biofilm, possibly a monolayer of *A. ferrooxidans* cells growing on the surface of an elemental sulfur prill. (d) Most of the biofilm of *A. ferrooxidans* seen in (c) was removed from the solid particle by using a detergent and vigorous shaking of the sample. The remaining cells seen in (c) and (d) by scanning electron microscopy. The arrows in each case point to electron dense polyphosphate granules that may help these microorganisms in their extremely high metal tolerance.

extraction of dissolved metal values from ores (Hedrich and Schippers, 2016). Since chalcopyrite it is the most difficult mineral to solubilize by microorganisms, there is actually great interest in developing processes by using thermophilic biomining microorganisms for these recalcitrant minerals. The extraction of copper from chalcopyrite by using bioreactors can be faster and efficient, and temperatures higher than 60°C can be used with thermophilic archaea such as *Sulfolobus metallicus*, *Metallosphaera sedula* and *Acidianus brierleyi* (Norris et al., 2013; Wheaton et al., 2015).

On the other hand, although no psychrophilic acidophiles (optimal growth temperature lower than 15 °C) have been reported some psychrotolerant microorganisms such as *Acidithiobacillus ferrivorans* have been isolated that can catalyze metal dissolution from sulfide minerals at 5°C. These bacteria are of importance in biomining operations since many of them are present in high altitudes and polar regions and therefore can be used for biotechnological operations in cold environments (Dopson, 2016a).

Industrial biomining operations are of several kinds depending on the ore type and its geographical location, the metal content, and the specific minerals present (metal oxides, metal sulfides of different kinds) (Walling, 2006). One of the most used setups for the recovery of gold or copper is the irrigation type of processes. These involve the percolation of leaching solutions through the crushed ore that can be contained in a column, a heap or a dump. In Fig. 3, we can see a scheme in which the crushed ore to bioleach is transported to an agglomeration tank or drum where it is acidified. This process is the key one since the bigger ore particles are surrounded by the very fine particles that stick to them thus preventing all the particles especially the fine material sediment to the bottom of the heap. In this way irrigation and aeration of the heap takes place from the top to the bottom, allowing a much more homogeneous growth of the microorganisms and therefore a better metal solubilization. The heap can be 6–10 m tall and 100 or more meters long and wide and is constructed over irrigation pads lined with high-density polyethylene to avoid losses of the pregnant copper-containing solution (Fig. 3). This solution containing copper sulfate generated by the microbial solubilization of the insoluble copper sulfides present in the ore is subjected to solvent extraction to have a highly concentrated copper sulfate solution from which the metal is recovered in an electrowinning plant to generate electrolytic copper of high purity (Fig. 3). Since most mining operations are located in areas where water is scarce, the spent leach liquors or raffinates are recirculated to the heap for further irrigation. This has to be controlled because the liquor is being enriched in salts that can rather select for those microorganisms able to stand the high salt and are not necessarily the most fit for the biooxidation reactions.

Bioleaching bacteria can also be used for gold recovery. Gold is usually found in nature associated with minerals containing arsenic and pyrites (arsenopyrites). During gold bioleaching, the iron- and sulfur-oxidizing microorganisms attack and solubilize the arsenopyrite releasing the trapped gold particles. Following this release, the gold is complexed with cyanide according to standard gold-mining procedures. Instead of using big leaching heaps or dumps as in the case of bioleaching of copper ores, gold bioleaching is usually done by using highly aerated stirred tank bioreactors connected in series. Since these reactors are expensive to

Fig. 3 A scheme showing the construction of a heap bioleaching process to obtain copper in a large scale.

build, they are used with high-grade ores or with mineral concentrates. The advantage of tank reactors over heaps and dumps, which are 'open bioreactors', is that in the tanks conditions can be controlled, thus having a much faster and efficient metal extraction process.

Currently, there are operations using both mesophilic and thermophilic microorganisms. Biomining has distinctive advantages over the traditional mining procedures (Harrison, 2016). For example, it does not require the high amounts of energy used during roasting and smelting and does not generate harmful gases such as sulfur dioxide. Nevertheless, AMD can be generated, which if not properly controlled, pollutes the environment with acid and metals. Biomining is also of great advantage since not only discarded low-grade ores from standard mining procedures can be leached in an economically feasible way but also some high-grade ores. In countries like Chile, which is actually the first world copper producer, many mining operations process from 10,000 to 40,000 tons of ore per day and produce between 10,000 and 200,000 tons of copper per year by using heap or dump bioleaching of minerals such as oxides, chalcocite, covellite, chalcopyrite, and others. Similar situations take place in United States, Australia, and other countries. The most successful ones have been those processing copper oxides and secondary copper sulfides. However, chalcopyrite is the most abundant copper sulfide in the world. Since it is the most difficult to be solubilized by microorganisms, there is actually great interest in developing processes mainly using thermophilic biomining microorganisms.

Acidiophilic Microorganism–Mineral Interaction

The microorganisms used in biomining belong to those known as extremophiles since they live in extremely acidic conditions (pH 1–3.0) and in the presence of very high toxic heavy metals concentrations. Considerable effort has been spent in the past few years to understand the biochemistry of iron and sulfur compounds oxidation, bacteria–mineral interactions, and the several adaptive responses that allow the microorganisms to survive in a bioleaching environment. All of these are considered key phenomena for understanding the process of biomining.

How do the bacterial cells recognize the site of attachment in the ores from which they will extract the metals? Do they have a specific way to detect or sense where the oxidizable substrate is present in the rocks? Ample evidence has shown that attachment of the bacterial cells to metal sulfides does not take place randomly. For example, *A. ferrooxidans* cells preferentially adhere to sites with visible surface scratches and it is seen to form pitting at the surface of minerals as already seen in Fig. 2.

Bacteria such as *Leptospirillum ferrooxidans* and *Acidithiobacillus thiooxidans* have been shown to possess a chemosensory system (Jerez, 2001) that allows them to have chemotaxis, that is, the capacity to detect gradients of oxidizable substrates being extracted from the ores such as Fe (ii)/Fe (iii) ions, thiosulfate, and others (Fig. 4). The response is the positive chemotactic attraction to the sites that will constitute specific favorable mineral attachment sites.

It is known that most leaching bacteria grow attached to the surface of the solid substrates such as elemental sulfur and metal sulfides. This attachment is predominantly mediated by extracellular polymeric substances (EPS) surrounding the cells and whose composition is adjusted according to the growth substrate (Fig. 4). Thus, planktonic or free-swimming cells grown with soluble substrates such as iron (ii) sulfate produce almost no EPS.

Biofilms are organized layers of bacteria associated to a solid surface by means of the matrix of EPS. The environment within this community favors intercellular interactions between bacteria (Orell and Guiliani, 2016). Thus, in the presence of oxygen or aerobiosis, *A. ferrooxidans* can respire this element and oxidize Fe (ii). Some of these microorganisms are also able to perform Fe (iii) respiration under anaerobiosis, regenerating Fe (ii) that can be used by those microbial cells closer to the oxygen within the biofilm structure. Other types of bacteria forming part of the microbial biofilm consortium will generate compounds useful to other

Fig. 4 A diagrammatic representation showing the main steps of the bacteria–mineral interaction. Details of the attack of the non-chemotactic *Acidithiobacillus ferrooxidans* on the mineral pyrite are shown in the amplified inset. The cell is embedded in an extracellular polymeric substances (EPS) biofilm in which the indirect mechanism generates ferrous iron and thiosulfate, which is finally oxidized to sulfuric acid. Inset Reproduced from Rohwerder et al. (2003).

members of the community and they can themselves benefit from the metabolic byproducts of other microbes present in the biofilm (Vera et al., 2013).

Several microorganisms are known to monitor their own population density through processes collectively described as quorum sensing (QS), and in several cases there is strong evidence indicating that biofilm formation is affected by QS. In most cases, specific genes within the bacterium are switched on at a defined population density (defined bacterial quorum) and the result obtained is the activation of functions under the control of a quorum sensor. In almost all cases, the capacity to detect a bacterium quorum depends on the release of a signal molecule from the microorganism that accumulates in proportion to the cell number (Fig. 4). Thus, QS represents a multicellular action in bacteria, where each cell communicates with each other to coordinate their behavior. It has been demonstrated that *A. ferrooxidans* not only contains quorum sensor signal molecules but also may induce the expression of genes related to QS and EPS production when grown attached to a solid substrate. Thus, modulation of the attachment of the microorganisms to ores through interferences of their QS responses can be envisaged as a new way to control metal extraction by these microorganisms (Farah et al., 2005).

A. ferrooxidans is also able to develop biofilm structures when growing in solid substrates such as elemental sulfur or metal sulfides and presents morphological modifications during the cellular adhesion process. For example, new proteins related to sulfur metabolism appear in the surface of *A. ferrooxidans* when grown in sulfur (Ramírez et al., 2002). This is clearly seen in Fig. 5, in

Fig. 5 Example of changes on the *Acidithiobacillus ferrooxidans* surface depending on growth conditions. It is known that *A. ferrooxidans* produces a protein in high amounts when the bacterium grows on elemental sulfur and not in ferrous iron (Fe). To see the location of that protein, an immunological system was used in which a gold particle (black dots) indicates the presence of the protein in the cells grown in ferrous iron (Fe) (a) or elemental sulfur (b).

which a primary antibody specific against a protein related to sulfur metabolism is bound to the surface of *A. ferrooxidans* cells grown in sulfur but is almost absent in ferrous iron-grown cells. The primary antibody bound to the protein was recognized by using a secondary antibody labeled with gold particles and specific to recognize the primary antibody bound to the sulfur-induced protein. The presence of the protein changing its expression is seen as the black dots of gold by transmission electron microscopy (TEM).

Mechanisms Involved in Metal Solubilization by Acidophiles

Traditionally, it has been proposed that microorganisms oxidize metal sulfides by either a direct or an indirect mechanism. In the first one, the bacteria have to attach to the mineral and the electrons would be directly extracted by an enzymatic reaction of the microorganism. However, there is no evidence how the bacteria break the metal–sulfide bond of a given mineral. In the indirect mechanism, the role of bacteria would be to oxidize ferrous ions present in the solution to ferric ions. Ferric ions are strong oxidants therefore will oxidize chemically the sulfide metals, being an indirect mode of attack. Actually, many researchers consider the existence of a contact mechanism, since the bacteria attaches to the surface of the mineral carrying Fe (iii) bound to its exopolysaccharides, and when the microorganism forms a biofilm being embedded in its EPS, this metal would chemically attack the metal sulfide generating, in the case of pyrite, ferrous iron that is reoxidized to Fe (iii) and thiosulfate that can be further oxidized to sulfuric acid (Fig. 4). The mechanism still is indirect (known also as indirect contact mechanism). This close contact of the bacterium with the mineral makes more efficient and specific the sulfide oxidation.

The insoluble metal sulfides are oxidized to soluble metal sulfates by the chemical action of ferric iron, the main role of the microorganisms being the reoxidation of the generated ferrous iron to obtain additional ferric iron (Fig. 4).

As already mentioned, *A. ferrooxidans* is a chemolithoautotrophic bacterium that obtains its energy from the oxidation of ferrous iron, elemental sulfur, or partially oxidized sulfur compounds and it has been considered as a model biomining microorganism. The reactions involved in ferrous iron oxidation by *A. ferrooxidans* have been studied in detail, however, the electron pathway from ferrous iron to oxygen has not been entirely established. The terminal electron acceptor is assumed to be a cytochrome oxidase anchored to the cytoplasmic membrane. The transfer of electrons would occur through several periplasmic carriers, including at least the blue copper protein rusticyanin and cytochrome c552. Recently, a high molecular weight c-type cytochrome, Cyc2, has been suggested to be the prime candidate for the initial electron acceptor in the respiratory pathway between ferrous iron and oxygen (Fig. 6). This pathway would be Cyc2 → rusticyanin → Cyc1(c552) → aa3 cytochrome oxidase. In addition, there is an apparent redundancy of electron transfer pathways via bc(1) complexes and terminal oxidases in *A. ferrooxidans* (Rawlings, 2005; Nitschke and Bonnefoy, 2016).

Fig. 6 Simplified model showing the main protein components (in red) present in the periphery of the cell and involved in the transfer of electrons from ferrous iron to oxygen and those oxidizing elemental sulfur (in yellow) and transferring the electrons to oxygen. This model represents the indirect mechanism of mineral attack by the ferric iron bound to the EPS of the *Acidithiobacillus ferrooxidans* cells. As an example, chalcopyrite is shown from which ferrous iron, copper (ii), and elemental sulfur are generated upon its oxidation. SDO, sulfur dioxigenase; SOR, sulfite oxidoreductase. Adapted from Rawlings, D.E., 2005. Characteristics and adaptability of iron- and sulfur-oxidizing microorganisms used for the recovery of metals from minerals and their concentrates. *Microbial Cell Factories* 4, 13.

As already mentioned, thiosulfate has been postulated as a key compound in the oxidation of the sulfur moiety of pyrite (Fig. 4). Iron (iii) ions are exclusively the oxidizing agents for the dissolution. Thiosulfate would be consequently degraded in a cyclic process to sulfate, with elemental sulfur being a side product. This explains why only Fe(ii) ion-oxidizing bacteria are capable of oxidizing these metal sulfides. All reactions comprising this oxidation have been shown to occur chemically. However, sulfur compound-oxidizing enzymes such as the tetrathionate hydrolase of *A. ferrooxidans*, *A. thiooxidans*, or *T. acidophilus* may also be involved in the process.

The oxidation of some metal sulfides such as chalcopyrite generates elemental sulfur as a side product instead of thiosulfate (Fig. 6). The aerobic oxidation of elemental sulfur by *A. ferrooxidans* and other microorganisms is carried out by a sulfur dioxygenase (SDO) and a sulfite oxidoreductase (SOR) (Fig. 6).

It is important to remark here that the ultimate oxidizing agent for iron (ii) and reduced inorganic sulfur compounds is oxygen, since often the transport of dissolved oxygen is the rate-limiting step in commercial bioleaching operations.

Biomining in the Postgenomic Era

Systems microbiology, which is part of systems biology, is a new way to approach research in biological systems. By this approach, it may be possible to explore the new properties of microorganisms that arise from the interplay of genes, proteins, other macromolecules, small molecules, and the environment. This is particularly possible today due to the large numbers of genomic sequences that are becoming increasingly available. However, additional genomic sequences of the different biomining microorganisms will be required to define the molecular adaptations to their environment and the interactions between the members of the community.

The use of genomics, metagenomics, proteomics and metaproteomics (Fig. 7), together with metabolomics to study the global regulatory responses that the biomining community uses to adapt to their changing environment is just beginning to emerge. These powerful OMICS approaches will have a key role in understanding the molecular mechanisms by which the microorganisms attack and solubilize ores. Furthermore, they offer the possibility of discovering exciting new findings that will allow analyzing the community as a microbial system, determining the extent to which each of the individual participants contributes to the process,

Fig. 7 Systems microbiology and the use of OMICS approaches to study microbial communities as applied to biomining microbes. Modified from Valenzuela, L., Chi, A., Beard, S., *et al.*, 2006. Genomics, metagenomics and proteomics in biomining microorganism. *Biotechnol. Adv.* 24, 197–211.

and how they evolve in time to keep the conglomerate healthy. This, taken together with the physicochemical, geological, and mineralogical aspects of the process, will allow improving the efficiency of this important biotechnology.

Biomining Community Diversity Analysis

Of extreme importance is not only to know the microorganisms present in a bioleaching operation, but to be able to monitor their behavior during the process, to determine the predominant species and the way they evolve in time with the changing environment as the metals are solubilized (Dopson, 2016b; Golyshina et al., 2016). In recent years, several molecular methods have been developed for other microorganisms and these have been successfully applied to many biomining operations. The most common techniques employed to explore the bacterial diversity use 16S rRNA and rDNA profiles and are culture-independent methods. Among these methods are included fluorescence in situ hybridization (FISH), denaturing gradient gel electrophoresis (DGGE), real time PCR, DNA microarrays, and others (Fig. 7).

Genomics

A. ferrooxidans was the first biomining microorganism whose genome was sequenced by TIGR. This information has been very useful to do genome-wide searches for candidate genes for important metabolic pathways and several important physiological functions, which can now be addressed. Furthermore, predictions for the functions of many new genes can be done. The main focus of research has been the energy metabolism that is directly responsible for bioleaching. Genes involved in phosphate, sulfur, and iron metabolism, QS, those potentially involved in several other functions such as metal resistance and amino acid biosynthesis pathways, and those involved in the formation of EPS precursors have been studied. Having the genomic sequence of a given biomining microorganism is very important, since it is then possible to formulate hypothesis about the regulation of the expression of most of these genes under different environmental conditions. Metabolic reconstruction and modeling provides an important preliminary step in understanding the unusual physiology of this extremophile especially given the severe difficulties involved in its genetic manipulation and biochemical analysis. However, all these bioinformatic predictions will have to be demonstrated experimentally by using functional genomics, proteomics, and other approaches. The existence of paralog genes that show sequence similarities but may have different functions in the same microorganism becomes obvious only when the genome sequence is available.

Currently, there are over 55 bacterial and 36 archaeal complete genome sequences from microorganisms that are present in biomining or AMD places (Cárdenas et al., 2016; Siezen and Wilson, 2009; Martínez et al., 2015). Some of the acidophilic microorganisms usually found in biomining or AMD places are for the bacteria *A. ferrooxidans*, *Leptospirillum* group II, and *Acidiphilium cryptum*. The genome sequences of *A. thiooxidans* and *A. caldus* have also been determined. Amongst the archaea, *Metallosphaera sedula* and *F. acidarmanus* genome sequences amongst several others are also available. *Sulfolobus acidocaldarius* and *Sulfolobus tokodaii* are also known, although they have not been reported as having a role in bioleaching. The generation of new DNA microarrays to monitor not only all the microorganisms present in samples from industrial operations (Fig. 7) but also specific genes such as those indicating the nutritional or stress state of the microorganisms or those involved in iron or sulfur compound oxidation whose products should predominate during different stages of active bioleaching (Parro and Moreno-Paz, 2003).

Functional Genomics

One of the most used techniques to study differential genome expression at the level of mRNA synthesis, transcriptomics, or the functional analysis of new and characterized genes is the use of DNA microarrays. The generation of new DNA microarrays and high throughput RNA sequencing can be used to monitor not only all the microorganisms present in samples from industrial operations but also specific genes such as those indicating the nutritional or stressing state of the microorganisms or those involved in iron or sulfur compound oxidation whose products will be predominant during different stages of active bioleaching.

The use of microarrays based on the entire genome of *A. ferrooxidans* and other microorganisms will enable a nearly complete view of gene expression of the members of the microbial community under several biomining conditions, helping to monitor their physiological state and adjustment made during the bioleaching process. A genome-wide microarray transcript profiling analysis (approximately 3000 genes of the *A. ferrooxidans* ATCC 23270 strain) has also been performed (Quatrini et al., 2006). The genes preferentially transcribed in ferrous iron growth conditions or in sulfur conditions were studied. The results obtained supported and extended models of iron and sulfur oxidation (Fig. 6) and supported the possible presence of alternate electron pathways and that the oxidation of these two kinds of oxidizable substrates may be coordinately regulated. By using the same approach, the expression of the genes involved in carbon metabolism of *A. ferrooxidans* has been studied in response to different oxidizable substrates.

As already mentioned, some mining companies are currently interested in doing transcriptomic analysis of their newly isolated microorganisms with improved capacities to leach copper since they already have obtained their genomic sequences (Latorre et al., 2016).

A very interesting alternative approach can be used to analyze gene function in environmental isolates without knowing the sequence of the microorganism of interest. A random genomic library from the isolated microorganism can be printed on a microarray. Gene expression by using total RNA extracted from the microorganism grown under different conditions can be determined. With this approach, it is possible to select and sequence only those clones bearing the genes that showed an altered expression pattern. Shotgun DNA microarrays are very powerful tools to study gene expression with environmental microorganisms whose genome sequence is still unknown.

Metagenomics

Metagenomics is the culture-independent genomic analysis of microbial communities. In conventional shotgun sequencing of microbial isolates, all shotgun fragments are derived from clones of the same genome. To analyze the genomes of an environmental microbial community (Fig. 7), the ideal situation is to have a low diversity environment. Such systems were found when analyzing the microbial communities inhabiting a site of extreme AMD production, in which few types of organisms were present. Still, variation within each species might complicate assembly of the DNA fragments. Nevertheless, random shotgun sequencing of DNA from this natural acidophilic biofilm was used. It was possible to reconstruct the near-complete genomes of *Leptospirillum* group II and *Ferropasma* type II and partially recover three other genomes. The extremely acidic conditions of the biofilm (pH about 0.5) and relatively restricted energy source combine to select for the small number of species found (Ram et al., 2005; Tyson et al., 2004; Baker and Banfield 2016).

The analysis of the gene complement for each organism revealed the metabolic pathways for carbon and nitrogen fixation and energy generation. For example, genes for biosynthesis of isoprenoid-based lipids and for a variety of proton efflux systems have been identified, providing insights into survival strategies in the extreme acidic environment. Clearly, the metagenomic approach for the study of microbial communities is a real advancement to fully understand how complex microbial communities function and how their component members interact within their niches. A full understanding of the biomining community also will require the use of all these current molecular approaches.

Proteomics

Proteomics provide direct information of the dynamic protein expression in tissue or whole cells, giving us a global analysis. Together with the significant accomplishments of genomics and bioinformatics, systematic analysis of all expressed cellular components has become a reality in the post genomic era, and attempts to grasp a comprehensive picture of biology have become possible.

One important aspect of proteomics is to characterize proteins differentially expressed by dissimilar cell types or cells imposed to different environmental conditions. Two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) in combination with mass spectrometry (MS) is currently the most widely used technology for comparative bacterial proteomics analysis (Fig. 7). The high reproducibility of 2D-PAGE is particularly valuable for multiple sample comparisons. In addition, it directly correlates the changes observed at the peptide level to individual protein isoforms (Remonsellez et al., 2016).

2D-PAGE separates a complex mixture of proteins such as those present in a bacterial cell extract based on the isoelectric point of the proteins in the first dimension (isoelectrofocusing gel). These proteins or groups of proteins are further resolved in a second dimension (SDS-PAGE), in which the proteins are all negatively charged and are separated based on their molecular masses (Fig. 7). Actual 2D-PAGE procedures can resolve around 1000 protein spots in a single run. One of the limitations of 2D-PAGE is that only the most abundant proteins in the cell can be detected. Therefore, to increase the resolution of the method, it is also possible to analyze a subproteomic cell fraction instead of the total cell proteins as shown for the periplasmic proteins from *A. ferrooxidans* (Chi et al., 2007).

The high reproducibility of 2D-PAGE is particularly valuable for multiple sample comparisons. In addition, it directly correlates the changes observed at the peptide level to individual protein isoforms. This is a typical 'reverse genetics' approach in which (after isolating from a 2D-PAGE gel) an individual protein is differentially expressed in a condition of interest, and the amino acid sequence of a peptide from the protein is obtained to identify its possible homologue in databases. With this information, its coding gene and genomic context can be searched using the genome DNA sequence (Fig. 7). Depending on these results, a suggested function could be hypothesized. It will be of great importance to demonstrate the expression of putative genes related to EPS synthesis in *A. ferrooxidans* cells grown on different metal sulfides and to find out if these genes are involved in cell attachment and biofilm formation. In this regard, *A. ferrooxidans* is known to form biofilms on solid substrates (Fig. 2). In an AMD biofilm analyzed by the proteomic approach, it was not known which microorganisms are responsible for the production of the polymer embedding the community. However, the presence of numerous glycosyltransferases and polysaccharide export proteins in the predominant bacterial species also suggests a role in biofilm formation.

Several studies have used 2D-PAGE to study changes in protein expression of *A. ferrooxidans* under different growth conditions. Proteins induced under heat shock, pH stress, phosphate limitation, or the presence of copper have been reported. A set of proteins that changed their levels of synthesis during growth of *A. ferrooxidans* in metal sulfides, thiosulfate, elemental sulfur, and ferrous iron has been characterized by using 2D-PAGE.

During growth of *A. ferrooxidans* in metal sulfides containing iron, such as pyrite and chalcopyrite, proteins upregulated both in ferrous iron and in sulfur compounds were synthesized, indicating that the two energy-generating pathways are simultaneously induced depending on the kind and concentration of the available oxidizable substrates.

The increasing number of sequenced genomes has provided good options for high-throughput functional analysis of proteomes. Proteomic studies are well advanced for diverse bacteria, such as the model bacterium *Escherichia coli* and others. Nevertheless, there is still a lack of data for identification of proteins from organisms with unannotated or unsequenced genomes, which makes large-scale microbial proteomics analysis a challenge. With the development of highly sensitive and accurate computational gene-finding methods, new microbial genomes could be explored and scientific knowledge of them could be maximized.

Traditional 2D gel electrophoresis coupled with MS is time consuming as a result of the nature of spot-by-spot analysis and it is biased against low abundance proteins, integral membrane proteins, and proteins with extreme pI or molecular weight (MW). Alternatively, solution-based approaches offer unbiased measurement of relative protein expression regardless of their abundance, subcellular localization, or physicochemical parameters (Fig. 7). This methodology, however, results in extremely complex samples. For instance, of the 4191 predicted genes in the complete genome of *E. coli*, 2800 of them are believed to be expressed at any one time. Additional complexity is introduced upon enzymatic digestion, which generates multiple peptide species for each protein. To obtain comprehensive protein expression information from the samples, a chromatographic separation step prior to MS protein analysis is often necessary. High performance liquid chromatography (HPLC) coupled with online electron spray ionization MS (ESI-MS/MS) has been proved to be a valid approach for analyzing protein expression in complex samples. Alternatively, Fourier transform ion cyclotron resonance mass spectrometer (FT-ICR MS) is well suited for the differential analysis of protein expression due to the high mass accuracy and high resolution as well as its inherent wide dynamic range. Peptide charge state can be readily derived with the accurate isotopic peak distribution information provided by FT MS experiment, and co-eluting species with the same nominal m/z ratio can be resolved. The differentially expressed m/z values identified can be assigned to the peptide sequences and, subsequently, differentially expressed proteins can be identified (Fig. 7).

In the periplasm of *A. ferrooxidans*, 216 proteins were identified, several of them changing their levels of synthesis when the bacterium was grown in thiosulfate, elemental sulfur, or ferrous iron media. Thirty four percent of them corresponded to unknown proteins. Forty one proteins were exclusively present in sulfur-grown and 14 in thiosulfate-grown cells. The putative genes coding for all the proteins were localized in the available genomic sequence of *A. ferrooxidans* ATCC 23270. The genomic context around several of these genes suggests their involvement in sulfur metabolism and possibly in sulfur oxidation and formation of Fe-S clusters (Chi et al., 2007).

Currently, quantitative proteomics has been quite useful with respect to better understanding global adaptations that acidophilic biomining microorganisms undergo in the presence of high metals concentrations and other stresses in their extreme environment (Remonsellez et al., 2016; Almárcegui et al., 2014; Martínez-Bussenius et al., 2017; Jerez, 2013).

Metaproteomics

The term 'metaproteomics' was proposed for the large-scale characterization of the entire protein complement of environmental microbiota at a given point in time. High-throughput MS has been used in a metaproteomic approach to study the community proteomics in a natural AMD microbial biofilm. Two thousand and thirty-three proteins from the five most abundant species in the biofilm were detected, including 48% of the predicted proteins from the dominant biofilm organism *Leptospirillum* group II. It was also possible to determine that one abundant novel protein was a cytochrome central to iron oxidation and AMD formation in the natural biofilm (Ram et al., 2005). This approach together with functional metagenomics can offer an integrated study of a microbial community to establish the role each of the participant plays and how they change under different conditions.

The goal of functional proteomics is to correlate the identification and analysis of distinct proteins with the function of genes or other proteins. With the discovery of a variety of modular protein domains that have specific binding partners, it has become clear that most proteins occur in protein complexes and that the understanding of a function of a protein within the cell requires the identification of its interacting partners. In the case of a biomining bacterium such as *A. ferrooxidans*, the identification of protein complexes involved in oxidative reactions is of high priority. What complexes are formed by cytochrome-like proteins such as rusticyanin (Rus in Fig. 6) with other proteins in the periplasm? Do some periplasmic proteins form a complex involved in sulfur compound oxidation in the periplasm? What other complexes of oxidative reactions are present in this microorganism? Proteomics may answer these and many other questions that will help to understand better the biomining process.

Some of the OMICS procedures briefly analyzed and summarized in Fig. 7 should be used in close conjunction with the known physiological functions of the microorganisms being studied. Metabolomics is also an important approach since it allows a global view of changes in the metabolism of cells under different conditions. This approach together with the other omics being used to study biomining microorganisms (Jerez, 2011) has been recently applied to industrially important bioleaching bacteria and unique metabolites found may be useful biomarkers to monitor and understand better the responses and adaptations of microorganisms to the stressing conditions present in industrial bioleaching operations.

It should be possible to better control the activity of the bacteria and archaea by giving them the appropriate nutritional and physicochemical conditions, and by interfering with some of these microbiological functions in order to enhance their action (for metal extraction) in the case of biomining or to inhibit their capacities to control AMD. As already mentioned (Fig. 4), some of these key physiological behaviors are chemotaxis, QS, and biofilm formation. Bacteria such as *A. thiooxidans* and *L. ferrooxidans* clearly

possess chemotactic systems and are attracted by a concentration gradient of thiosulfate or ferrous iron such as the one generated on the surface of pyrite (Fig. 4). This sensing ability is very important for the specific bacterial adherence at the places where the substrates to be solubilized through oxidation are present.

The development of efficient transformation or conjugation systems to introduce DNA to generate mutations affecting a gene of interest by using gene knockout systems is still almost entirely lacking for biomining microorganisms. These tools will be essential not only to perform functional genomics and have experimental demonstrations for the suggested gene functions based on bioinformatics analysis of the postgenomic data, but also to eventually improve some physiological bacterial capabilities. At the same time, the new OMICS methods are greatly helping to monitor more precisely the biomining consortia, and it is expected that providing the right physiological conditions to the community together with proper chemical or physical manipulations of the bacterial environment will further improve bioleaching rates in biomining operations.

Environmental Effects of Metals Solubilization and Bioremediation

The acidophilic microorganisms mentioned, mobilize metals and generate AMD, causing serious environmental problems. AMD should be remediated or abated. Often there is a sealing of the contaminated sites or the location of barriers to contain the acidic fluids (Jerez, 2009). Many approaches use prevention techniques to avoid further spillage of acidic effluents in the contaminated area. It can be controlled by chemical treatments such as the use of calcium oxide that neutralizes the acid pH. It is also possible to inhibit the acidophilic microorganisms responsible of the acid generation. This can be done by using certain organic acids, sodium benzoate, sodium lauryl sulfate, or quaternary ammonium compounds that will affect the growth of bacteria such as *A. ferrooxidans*.

Bioremediation or removal of the toxic metals from these contaminated soils can be achieved by a very interesting combination of two opposite biological activities: that of sulfur-oxidizing bacteria with the one of sulfate-reducing microorganisms. In a first step, the sulfur-oxidizing bacteria generate sulfuric acid which bioleaches or solubilizes the metals in the solid phase of the soil. The leachate metals are then precipitated in a second step by using a bioreactor in which the hydrogen sulfide generated by the sulfate-reducing bacteria under neutral and anaerobic conditions forms insoluble metal sulfides, which are eliminated (Fig. 8) (Lloyd et al., 2005). Metal contaminants such as Cu, Cd, Ni, and others can be efficiently leached from contaminated soils. The effluents obtained from such a process are clean enough of the metals that they can be reused in the environment.

Bioleaching microorganisms such as *A. ferrooxidans* can also have other uses to help avoiding metal contaminations in modern societies. For example, this bacterium has been successfully used to recover metals such as cadmium from spent batteries. By using bioreactors, *A. ferrooxidans* is grown attached on elemental sulfur. The bacteria generate sulfuric acid through the oxidation of sulfur that is then used for the indirect dissolution of spent nickel–cadmium batteries recovering after 93 days 90–100% of cadmium, nickel, and iron. Bioleaching of spent lithium ion secondary batteries, containing lithium and cobalt, has also been explored. These approaches are not only economically valuable but may be an effective method which could be considered the first step to recycle spent and discarded batteries preventing one of the many problems of environmental pollution (Jerez, 2009, 2011).

Fig. 8 A schematic diagram illustrating a process for the bioremediation of soils polluted with metals.

Conclusions

Microorganisms (Bacteria and Archaea) require several metals that are essential for their life. However, when the metal concentrations reach toxic levels, they also possess metal resistance mechanisms that involve active efflux or a detoxification of metal ions by different transformations. They can transform most toxic metals to less soluble or less volatile forms by intracellular complexation, decreased accumulation, extracellular complexation, or sequestration in the periplasm. Some of these activities result in the solubilization or extraction of metals, which are successfully used in environmental biotechnological applications.

The aerobic mineral oxidation or the anaerobic respiration of different microorganisms can result in the solubilization or extraction of metals. All these bacteria-metal interactions are part of the normal biogeochemical processes in nature.

The microbial solubilization of metals in acid environments is successfully used in industrial processes called bioleaching of ores or biomining, to extract metals such as copper, gold, uranium and others. On the contrary, the acidophilic microorganisms mobilize metals and generate AMD, causing serious environmental problems. However, bioremediation or removal of the toxic metals from contaminated soils can be achieved by using the specific properties of microorganisms interacting with metals.

Current approaches to study microorganisms consider the microorganism or the community as a whole, integrating fundamental biological knowledge with genomics, proteomics, metabolomics, and other data to obtain a global picture of how a microbial cell or a community functions. This new knowledge will help not only in understanding microbiological phenomena but it will be also useful to improve applied microbial biotechnologies.

Glossary

Acetotrophic methanogen Methanogen that catabolizes acetate to CH₄ and CO₂.

Coenzyme M Coenzyme that serves as the carbon carrier during the final reduction of bound CH₃ to CH₄.

DNA/RNA polymerases Enzymes that catalyze the synthesis of DNA or RNA, respectively, from a DNA template.

H₂-consuming acetogen Microorganism that synthesizes acetate from H₂ and CO₂.

H₂-producing acetogen Microorganism that generates H₂ by oxidizing short-chain fatty acids or alcohols.

Hydrogenotrophic methanogen Methanogen that generates methane by the reduction of CO₂ with H₂.

Interspecies H₂ transfer Mutually beneficial transfer of H₂ from H₂-producing microorganisms to H₂-consuming microorganisms in an anaerobic ecosystem.

Methanofuran Coenzyme that serves as a carbon carrier during the initial reduction of CO₂ in the methanogenic pathway.

Methylotrophic methanogen Methanogen that generates methane by reduction of methyl groups.

Obligate syntroph Microorganism that must interact mutualistically with one or more other microorganisms to metabolize a specific substrate; specifically refers to interspecies H₂ exchange in this article.

Restriction endonuclease Enzyme that protects organisms by degrading ('restricting') foreign DNA that enters the cell.

Tetrahydromethanopterin Coenzyme that serves as the carbon carrier during sequential reduction of bound CO₂ to CH₃.

Abbreviations

BRE	B recognition element
CoA	Coenzyme A
CRISPRs	Clustered regularly interspaced short palindromic repeats
H ₄ MPT	Tetramethanopterin
H ₄ THF	Tetrahydrofolate
H ₄ SPT	Tetrahydrosarcinapterin
MCM	Minichromosome maintenance
MFR	Methanofuran
MT1	Methanol:5-hydroxybenzimidazolyl
MT2	Methylcobamide:CoM methyltransferase
NAD	Nicotinamide adenine dinucleotide
RNAP II	RNA polymerase II
TCA	Tricarboxylic acid
TFB	Transcription factor B
TFE	Transcription factor E
tRNA	Transfer RNA
5'-UTR	5' untranslated region
%G + C	Percentage guanosine + cytosine

Historical Overview

The generation of combustible gas, presumably CH₄, has been reported by Pliny as early as during the Roman Empire. Legendary manifestations of methanogenesis include the will-o'-the-wisp, hypothesized to have resulted from the spontaneous combustion of marsh gas, and fire-breathing dragons, conjectured to have resulted from the accidental ignition of gas from CH₄-belching ruminants. The close association between decaying plant material and the generation of 'combustible air' was first described by the Italian physicist Alessandro Volta in 1776, when he reported that gas released after disturbing marsh and lake sediments

[☆]*Change History:* August 2014. K Sowers changed address to Institute of Marine & Environmental Technology, University of Maryland, updated and reduced length of abstract, updated text, references, tables, and figures.

produced a blue flame when ignited by a candle. Bechamp, a student of Pasteur, was the first to establish that methanogenesis was a microbial process, which was corroborated by others throughout the remainder of the nineteenth and early twentieth centuries. Because of the methanogens' requirement for strict anaerobic conditions, the first isolates were not reported until the 1940s. The approach used for isolation, the shake culture, involved adding microorganisms to molten agar growth medium containing a chemical reductant, such as pyrogallol carbonate, to prevent O_2 from diffusing into the agar. However, this approach was not suitable for isolating and maintaining methanogens in pure culture for long periods of time, as the medium was not sufficiently anaerobic. It was not until 1950 that a simple, effective technique was developed that provided the rigorous conditions required for routine isolation and culturing of methanogenic *Archaea* (Figure 1). The technique, referred to as the 'Hungate technique', employs gassing cannula, O_2 -free gases, and cysteine-sulfide reducing buffers to prepare a highly reduced, O_2 -free medium. Boiling initially deoxygenates medium, and a cannula connected to an anaerobic gas line, such as N_2 or CO_2 , is inserted into the vessel to displace air as the medium cools. The medium is dispensed into culture tubes or serum vials while purging with anaerobic gas and then the medium is sealed with a rubber stopper or septum. The vessel containing reduced medium and anaerobic gas effectively becomes an anaerobic chamber for culture growth. The development of the anaerobic glove box has further simplified culturing of methanogens by providing a means for colony isolation in Petri plates containing anaerobic medium solidified with agar (Figure 2). Inoculated plates are then transferred to an anaerobe jar that is purged with anaerobic gas and hydrogen sulfide to create conditions necessary for growth.

Diversity and Phylogeny

The methanogens are members of the *Archaea*, one of three domains of life proposed by C. Woese on the basis of 16S rRNA sequence, which also include the *Bacteria* and *Eukarya* (Figure 3). *Archaea* have morphological features that resemble the *Bacteria*; they are unicellular microorganisms that lack a nuclear membrane and intracellular compartmentalization. In contrast, several

Figure 2 Anaerobic glove box used for growing methanogens. Materials are introduced into the glove box through an air lock located on the side.

Figure 3 Phylogenetic tree based on 16S rRNA sequence showing selected genera of methanogens within one of the two major phyla of *Archaea*, the *Euryarchaeota*.

molecular features of the *Archaea* have similarity to the *Eukarya*; these features include histone-like DNA proteins, a large multicomponent RNA polymerase, and eukarya-like transcription initiation. Despite the similarities to the other domains, *Archaea* also have unique characteristics that distinguish them from the *Bacteria* and *Eukarya*. These distinguishing features include membranes composed of isoprenoids ether linked to glycerol or carbohydrates, cell walls that lack peptidoglycan, synthesis of unique enzymes, and enzyme cofactor molecules. An additional unifying characteristic among the *Archaea* is their requirement for extreme growth conditions, such as high temperatures, extreme salinity, and, in the case of the methanogens, highly reduced, anoxic environments.

Although the methanogens are a phylogenetically coherent group and have a limited substrate range, they are morphologically and physiologically diverse. They include psychrophilic species from Antarctica that grow at 1.7 °C to extremely thermophilic species from deep submarine vents that grow at 110 °C; acidophiles from marine vents that grow at pH 5.0 to alkaliphiles from alkaline lake sediments that grow at pH 10.3; species from freshwater lake sediments that grow at saline concentrations below 0.1 mol l⁻¹ to extreme halophiles from solar salterns that grow at nearly saturated NaCl concentrations; autotrophs that use only CO₂ for cell carbon and methylotrophs that utilize methylated compounds. Despite the range and diversity of growth habitats where methanogens are found, methanogens have one common attribute: they all generate CH₄ during growth.

There are currently over 140 described species of methanogens in six orders within the archaeal kingdom *Euryarchaeota* (Figure 3). Characteristics of methanogenic *Archaea* are described in Table 1.

The order *Methanococcales* includes marine autotrophs that grow exclusively by CO₂ reduction with H₂ or in some cases use formate for growth and methanogenesis. Morphologically, these species form irregularly shaped cocci. Instead of a rigid cell wall, typical of most *Bacteria*, these species form an S-layer, composed of an array of protein subunits, and are subject to osmotic lysis at NaCl concentrations below seawater. This order includes several mesophilic *Methanococcus* spp., moderately thermophilic *Methanothermococcus* spp., and the extremely thermophilic genera *Methanocaldococcus* and *Methanotorris*.

The order *Methanobacteriales* is predominantly composed of rod-shaped cells that grow by CO₂ reduction with H₂. One exception is the genus *Methanospaera*, which grows as cocci and uses H₂ to reduce the methyl group of methanol instead of CO₂. Other species can also reduce methyl groups with hydrogen, oxidize alcohols to reduce CO₂ or use formate for growth and methanogenesis. Cells have a rigid cell wall approximately 15–20 nm thick and, when stained for thin-section electron microscopy, resemble the electron-dense monolayer cell wall of Gram-positive bacteria. These archaeal cell walls are composed of pseudomurein, which is chemically distinguishable from bacterial murein by the substitution of *N*-talosaminuronic acid for *N*-acetylmuramic acid and substitution of β(1,3) for β(1,4) linkage in the glycan strands, and substitution of D-amino acids for L-amino acids in the peptide cross-linkage. *Methanothermus* spp. also have an additional cell wall layer, composed of glycoprotein S-layer that surrounds the pseudomurein. *Methanobrevibacter* spp. are all mesophilic; *Methanobacterium* includes mesophiles and moderate thermophiles with optimal growth temperatures as high as 65 °C; *Methanothermobacter* spp. are exclusively moderate thermophiles, and *Methanothermus* species are extreme thermophiles, with maximum growth temperatures as high as 97 °C.

Table 1 Description of methanogenic Archaea

Taxonomic epithet	Morphology	Substrates ^a	Optimum growth conditions		Isolation source

^bOnly one range reported.

The order *Methanomicrobiales* contains genera that are diverse in morphology and physiology. Most species grow as cocci and rods. In addition, *Methanoplanus* forms flat plate-like cells with characteristically angular ends. Another species, *Methanospirillum hungatei*, forms a helical spiral. The cell walls in this order are composed of a protein S-layer and are sensitive to osmotic shock or detergents. In addition to the S-layer, *M. hungatei* also has an external sheath that is composed of concentric rings stacked together. Species range from nonhalophilic to slightly halophilic. Temperature tolerances include the only currently described psychrophile, *Methanogenium frigidum*, mesophiles, and moderate thermophiles. Most species grow by CO₂ reduction with H₂, but some species also use formate or secondary alcohols as electron donors for CO₂ reduction.

The order *Methanosarcinales* includes the most catabolically diverse species of methanogens. Whereas most methanogenic species grow by obligate CO₂ reduction with H₂, species within this order can also grow by methyl reduction with H₂, acetate fermentation of acetate, or methylotrophic catabolism of methanol, methylated amines, and dimethylsulfide. *Methanosarcina acetivorans* was recently reported to grow also with CO by conversion to acetate and formate, rather than methane, as the major metabolic end products. Whereas some species of *Methanosarcina* can grow by all five catabolic pathways, *Methanosaeta* species are obligate acetotrophs and all other genera are obligate methylotrophs. All species have a protein S-layer cell wall and most species grow as irregularly shaped cocci. However, several species of *Methanosarcina* also synthesize a heteropolysaccharide matrix external to the S-layer. This external layer can be up to 200 nm thick and is primarily composed of a nonsulfonated polymer of N-acetylgalactosamine and D-glucuronic or D-galacturonic acids. The matrix is called methanochondroitin because of its chemical similarity to a mammalian connective tissue component, known as chondroitin. At freshwater NaCl concentrations, *Methanosarcina* spp. that synthesize methanochondroitin grow in multicellular aggregates rather than as single cells, but when grown at marine salt concentrations or with high concentrations of divalent cations, such as Mg²⁺, they no longer synthesize methanochondroitin and grow as single cells. *Methanosaeta* species have an external sheath that appears similar in structure to that described for *M. hungatei*.

Two orders presently include only one described genus. The order *Methanocellales* was proposed for species within a clonal lineage identified as 'rice cluster I'. This order currently includes three isolated species within the genus, *Methanocella*.

These hydrogenotrophic rod-shaped species have all been isolated thus far from rice fields. The order *Methanopyrales* is the most deeply branching methanogenic archaeon and presently includes only one species, *Methanopyrus kandleri*. This hyperthermophilic species is an obligate hydrogenotroph and grows as a rod with a pseudomurein cell wall surrounded by a protein S-layer, similar to that described for *Methanothermus*.

Habitats

Interspecies H₂ Transfer

As described above, methanogens utilize a limited number of simple substrates. In most habitats, they depend on other anaerobes to convert complex organic matter into substrates, which they can catabolize. Therefore, unlike aerobic habitats, where a single microorganism can catalyze the mineralization of a polymer by oxidation to H₂O and CO₂, degradation in anaerobic habitats requires consortia of interacting microorganisms to convert polymers to CH₄ and CO₂. These interactions are dynamic with the methanogens affecting the pathway of electron flow, and, consequently, carbon flow, by a process called interspecies H₂ transfer. In this association, the H₂-utilizing methanogens maintain a low H₂ partial pressure that allows certain reactions that do not occur under standard conditions to be thermodynamically favorable. One physiological group of microorganisms affected by this process is the H₂-producing acetogens. The reactions carried out by these microorganisms for growth are not thermodynamically favorable (i.e., $+\Delta G^\circ$; under physiological growth conditions), as the H₂ they generate accumulates and growth is subsequently inhibited. However, in association with H₂-consuming microorganisms, such as the methanogens, the H₂ partial pressure is maintained at levels low enough to make the reaction thermodynamically favorable (i.e., $-\Delta G^\circ$; under physiological growth conditions). Because of their dependence on the H₂-consuming microorganisms, the H₂-producing acetogens are often referred to as obligate syntrophs.

Another physiological group of microorganisms affected by interspecies H₂ transfer is the fermentative anaerobes that synthesize a hydrogenase. In many of these microorganisms, substrate oxidation is linked to the electron carrier nicotinamide adenine dinucleotide (NAD), which has higher redox potential (−320 mv) than H₂ (−414 mv) under standard conditions. However, if the H₂ partial pressure is maintained at a low level (<10 Pa) by H₂-utilizing microorganisms, then H₂ production from NAD becomes thermodynamically favorable. This enables the fermentative microorganisms to reoxidize NADH by reducing protons to form H₂ rather than reducing pyruvate to form dicarboxylic acids and alcohols. This synergistic process enables the fermentor to conserve ATP by synthesizing more acetate and less further reduced products. In addition, the net products, acetate and H₂, serve as substrates for growth by the methanogen. The result is that carbon and electron flow is directed toward more efficient degradation by the consortium to the gases CH₄ and CO₂. CO₂ reenters the carbon cycle directly and CH₄ is either oxidized by methylotrophs to CO₂ as it diffuses into the aerobic zone or it enters the atmosphere.

Synergistic interspecies substrate transfer has also been reported to occur with formate and acetate. Removal of formate by formate-utilizing methanogens and the removal of acetate by acetotrophic methanogens have been shown to create a thermodynamic shift that favors butyrate and propionate degradation in syntrophic cocultures of acetogenic *Bacteria* and methanogenic *Archaea*.

Freshwater Sediments

As organic matter accumulates on lake and river basins, the sediment becomes anaerobic, because oxygen is depleted by the activities of aerobic microorganisms. In eutrophic environments with high organic loading, the anaerobic region occurs immediately below the sediment surface and even into the water column if the activities of the aerobic microorganisms exceed the rate of oxygen diffusion. Once oxygen and alternative electron acceptors such as NO₃[−], Fe³⁺, Mn⁴⁺, and SO₄^{2−} are depleted, methanogenesis becomes the ultimate degradative process. The flow of carbon in anaerobic freshwater sediments is shown in Figure 4. Fermentative bacteria that synthesize hydrolytic enzymes, such as cellulases, proteases, amylases, and lipases, catalyze degradation of complex polymers to soluble monomers. The fermentative bacteria then ferment the soluble products to H₂, CO₂, simple alcohols, and fatty acids, including significant generation of acetate, due to interspecies H₂ transfer. H₂-producing acetogenic bacteria then catalyze the oxidation of alcohols and fatty acids to H₂, CO₂, and acetate. The third consortium group of microorganisms, the methanogenic *Archaea*, utilizes the simple substrates H₂, CO₂, and acetate generated by the fermentative and acetogenic bacteria, to generate CH₄. The net result of this consortium is that carbon and electrons are directed toward the synthesis of CH₄ and CO₂, which then reenter the global carbon cycle. CH₄ is oxidized by aerobic methanotrophic bacteria as it diffuses through the aerobic regions of the water column and reenters the atmosphere as CO₂. However, some CH₄ escapes from shallow water bodies, such as rice fields, through the vascular systems of aquatic plants, and enters the atmosphere as a greenhouse gas.

Anaerobic Bioreactors

Methanogenic bioreactors are used for the conversion of organic wastes to CH₄ and CO₂. These anaerobic digestors are found in nearly all sewage treatment plants where wastes in the form of sewage sludge, polymeric particulate material generated by settling of raw sewage, are converted to CH₄ and CO₂ by a consortium of microorganisms in freshwater sediments similar to that previously described. In contrast to most sediment environments, microbial metabolism is higher in a bioreactor because of greater rates of

Figure 4 Carbon flow in an anaerobic microbial consortium from freshwater sediments.

organic loading and higher temperatures (35–40 °C) generated by heating the reactor, often by combusting the CH₄ generated in the degradative process. As a result, the rate-limiting factor in a bioreactor is the slow growth rates of the acid-consuming H₂-producing acetogens and the acetate-utilizing methanogens, which require retention times of 14 days or more, to compensate for their slow metabolic activities. Another critical factor is the requirement for H₂-utilizing methanogens to maintain H₂-partial pressures below 10 Pa. Perturbations in the process that result in inhibition and subsequent ‘washout’ of either of these metabolic groups will result in a drop in pH, resulting in acid accumulation and subsequent inhibition of the entire reactor process. Perturbations can include sudden overloading with a readily fermented organic substrate that results in rapid accumulation of H₂ and fatty acids or introduction of a toxic compound that disrupts the microbial balance.

Anaerobic bioreactors have also been tested as a low-cost method for treatment of other types of particulate organic wastes, including animal manure and crop wastes. Nonparticulate industrial wastes, including many food processing by-products, and organic solvents, such as chlorinated aliphatic and aromatic compounds, are often too dilute to be economically treated by standard bioreactor configurations, which would require long retention times. In order to decrease the hydraulic retention time of the waste without washing out the biomass, high-rate anaerobic bioreactor configurations have been developed. Examples of these reactors include fixed-film reactors, in which biofilms of microbial consortia are retained in the vessel on solid supports, such as plastic or ceramic matrixes, glass beads, or sand grains. Other designs exist, such as the anaerobic upflow sludge blanket process, in which biomass is immobilized by the aggregation of microbial consortia into distinct granules (Figure 5). The granules usually consist of three discrete layers of microorganisms that include acetate-utilizing methanogens in the interior, H₂-producing acetogens and H₂-utilizing methanogens in the middle layer, and fermentative microorganisms in the outermost layer. Settler screens separate the granules from the treated water and gas is collected at the top of the reactor. In contrast to particulate waste reactors, in which microbial biomass is generated at the same rate of hydraulic washout, requiring retention times as long as several days, growth of biomass in these high-rate reactors is uncoupled from retention time of the waste and can have retention times as short as 1 h. Hydraulic retention times have also been reduced further in anaerobic fermentors that operate at temperatures of up to 60 °C, since the metabolic rates of thermophilic microorganisms, including acetate-utilizing methanogens, are greater than those of mesophiles.

Marine Habitats

In marine habitats where substrates are often limited, sulfate-reducing bacteria outcompete methanogens as the terminal members of the anaerobic consortium (Figure 6). Their predominance is a result of the availability of the electron acceptor sulfate in seawater (~30 mmol l⁻¹). Their lower *K_s* for substrate utilization enables the sulfate-reducing bacteria to use low concentrations of H₂ and acetate at rates that are greater than those of methanogens. However, methanogenesis is predominant in marine environments where SO₄²⁻ has been depleted. These environments include the lower depths of sediments and elevated coastal marshes, where the rate of SO₄²⁻ reduction is greater than the rate of diffusion from seawater, and also sediments that receive large amounts of organic matter, such as eutrophic coastal regions and submarine trenches. In these regions, the three-member methanogenic consortium is similar to that in freshwater environments, but it is composed of halophilic and halotolerant species. Although the acetotrophic

Figure 6 Carbon flow in an anaerobic microbial consortium from marine sediments.

methanogens *Methanosarcina* and *Methanosaeta* have been isolated from marine methanogenic enrichments, isotope studies performed in sediment suggest that most of the acetate is oxidized by an H₂-producing syntroph rather than by fermentation to CH₄. Methanogens also generate CH₄ from methylated amines and thiols, which are readily available in the marine environment as metabolic osmolytes. Since methylated amines are not used by SO₄²⁻-reducing bacteria, this class of compound is 'noncompetitive' and can be used by methanogens in habitats that contain high SO₄²⁻ concentrations.

CH₄ generated in sediments is often consumed as it diffuses through the SO₄²⁻-reducing region of the sediments, before reaching the aerobic regions. Although the microbes that catalyze this anaerobic oxidation have not been isolated, analysis by fluorescence *in situ* hybridization with species-specific probes indicates that the methane is oxidized by a consortium of two microorganisms: a methanogen that oxidizes the methane by reverse methanogenesis coupled by an unknown intermediate to sulfate reduction by a sulfate-reducing bacterium. The metagenome and mRNA expression analysis of the microbial consortia mediating the anaerobic oxidation of methane with sulfate (ANME) are consistent with acetate and formate as putative electron shuttles. Expression of putative secreted multiheme c-type cytochromes suggests direct electron transfer as an additional possible mode to shuttle electrons from ANME-1 to the bacterial sulfate-reducing partner, but a methanogenic isolate and confirmation of

the actual mechanism for this anaerobic process remain elusive. Although much of the CH_4 generated in sediments is consumed in the SO_4^{2-} -reducing regions, the water column in the open ocean is supersaturated with CH_4 , compared with the atmospheric concentration. This may result from a combination of unoxidized CH_4 that escapes from sediments, the activity of microbial communities in planktonic aggregates known as marine snow, and methanogenic activity in the gastrointestinal tracts and fecal material of marine animals. Biologically generated CH_4 in some organic-rich buried sediments can accumulate as gas deposits. Since natural gas deposits generated abiotically are used as indicators of petroleum, these biologically generated CH_4 deposits can act as false indicators of petroleum deposits during oil exploration. Under high hydrostatic pressures generated in deep-ocean sediments, biogenic CH_4 can accumulate also as solidified CH_4 hydrates.

Ruminant Animals

Ruminant animals include both domestic (e.g., cows, sheep, and camels) and wild (e.g., deer, bison, and giraffes) animals. These animals have a large chamber, called the rumen, before the stomach, in which polymers, such as cellulose, are fermented by bacteria to short-chain fatty acids, H_2 , CO_2 , and CH_4 . The rumen is similar to an anaerobic bioreactor, except that the short retention time created by swallowing saliva is less than the generation time of H_2 -producing fatty acid oxidizers and acetate-utilizing methanogens (Figure 7). As a result, acetate, propionate, and butyrate are not degraded by the consortium, but are absorbed into the bloodstream of the host animal as carbon and energy sources. The volatile gases (e.g., CH_4 , CO_2) are removed from the animal by belching. Acidification of the system by the acids is prevented by bicarbonate in the saliva of the animal. Carbon diverted to CH_4 and belched into the atmosphere represents a loss of energy to the animal and a significant global source of greenhouse gas emissions. Ruminant nutritionists have been attempting to increase feed efficiency by adding methanogenic inhibitors, such as monensin, to feed, thereby, diverting carbon flow to metabolites that can be utilized by the animal. One approach currently being tested is to target specific methanogen proteins with antibodies and harness the immune system of ruminants to increase feed efficiency and mitigate greenhouse gas emissions from agriculture.

Xylophagous Termites

All known termites harbor a dense microbial community of anaerobic bacteria, and, in the case of lower termites, they also contain cellulolytic protozoa that catalyze the digestion of lignocellulose from wood. As in the rumen, these microorganisms have a synergistic relationship with the termites by converting polymers to short-chain fatty acids that are used as carbon and energy sources for their host. The carbon flow in the hindgut of soil-feeding and fungus-cultivating termites is similar to that in rumen, but in wood- and grass-eating termites, most H_2 - CO_2 is converted to acetate instead of CH_4 . Generally, methanogenesis outcompetes H_2 - CO_2 acetogenesis and the factors that cause the predominance of acetogenesis in some termites is not known. Three species of H_2 -utilizing *Methanobrevibacter* have been isolated from the hindgut of the subterranean termite that exhibit catalase activity and are particularly tolerant to oxygen exposure. Oxygen tolerance may be important for recolonization by bacterial consortia after expulsion of the hindgut contents during molting. Reinoculation is achieved by transfer of hindgut contents from other colony members, which are exposed to air during the process.

Figure 7 Carbon flow in an anaerobic microbial consortium from the rumen.

Protozoan Endosymbionts

Methanogens are present as endosymbionts in many free-living marine and freshwater anaerobic protozoa, where they are often closely associated with hydrogenosomes, organelles that produce H_2 , CO_2 , and acetate from the fermentation of polymeric substrates. The products of the hydrogenosomes are substrates for methanogenesis. It is conceivable that the methanogens have a synergistic role by lowering the H_2 partial pressure to create a favorable thermodynamic shift in the protozoan's fermentation reaction. Also, evidence suggests that excretion of undefined organic compounds by the methanogen provides an advantage to the protist host. Endosymbionts are also found in flagellates and ciliates that occur in the hindgut of insects, such as termites, cockroaches, and tropical millipedes. Although rumen ciliates do not harbor endosymbiotic methanogens, many have ectosymbiotic methanogens that may have an analogous function.

Colonization in Humans

The human colon serves as a form of hindgut where undigested polymers and sloughed off intestinal epithelium and mucin are dewatered, fermented by bacterial consortia, treated with bile acids, and held until defecation. Fatty acids generated by fermentation are absorbed into the bloodstream and can provide approximately 10% of human nutritional needs. Methanogenesis occurs in 30–40% of the human population, with the remaining population producing H_2 and CO_2 instead. Acetogenesis and SO_4^{2-} reduction from H_2 - CO_2 also occur in the human colon, but studies with colonic bacterial communities suggest that these activities are only prevalent in the absence of methanogenic activity. The level of CH_4 produced by an individual corresponds to the population levels of *Methanobrevibacter*, but factors controlling the occurrence of methanogens in the human population are not known. Diet does not appear to have a significant role in determining whether an individual harbors an active methanogenic population, but hereditary and individual physiological factors might have a role. For example, methanogens might be absent from individuals who excrete higher levels of bile acids, which are inhibitory to methanogens. Methanogenic *Archaea* have also been isolated from the human vagina and oral cavity.

Epidemiological studies have revealed a relationship between the severity of periodontal disease and the relative abundance of *Methanobrevibacter*-like phylotypes. It has been suggested that the methanogens have a syntrophic relationship with periodontitis-causing fermentative bacteria that promotes their colonization. There have also been studies that show an increase in methanogenesis associated with colon cancer patients, but other reports contradict these conclusions. Although annotation of methanogen genomes reveals properties characteristic of many pathogenic bacteria including putative RelBE toxin/antitoxin genes and evidence of lateral gene transfer with bacteria, methanogens have not been shown unequivocally to cause or promote human disease.

Other Habitats

Habitats that have a source of organic carbon and high water content can become anaerobic as a result of respiratory depletion of oxygen, and, subsequently, support methanogenic communities. Examples include soils waterlogged by heavy rainfall, marshes, rice paddies, rotting heartwood of trees, and landfills. Most of the CH_4 generated in these habitats is released into the atmosphere. However, many landfills are now vented to prevent a buildup of potentially combustible CH_4 underground or in nearby dwellings, and some communities harvest the vented biogas for heat and energy.

Methanogenic habitats are also found in geo-hydrothermal outcrops, such as terrestrial hot springs and deep-sea hydrothermal vents. Methanogens from these environments use geothermally generated H_2 - CO_2 for methanogenesis and most are hyperthermophilic, requiring growth temperatures as high as 110 °C. In terrestrial sites, methanogens are usually associated with microbial mats composed of photosynthetic and heterotrophic consortia. However, in deep-sea hydrothermal vents, where there is no light available for photosynthetic production of organic carbon, the methanogens and other autotrophic bacteria serve as primary producers of cell carbon for a complex community of heterotrophic microbes and animals that accumulates in the vicinity of a hydrothermal vent.

Methanogenesis occurs in high-saline environments, such as Great Salt Lake, Utah, Mono Lake, California, and solar salt ponds. Methanogens from these environments generate CH_4 from methylated amines and dimethylsulfide, which are synthesized by animals and plants as osmolytes. Methanogenesis has been detected in subsurface aquifers over 400 m deep, where it has been proposed that H_2 generated by an abiotic reaction between iron-rich minerals in basalt and ground water is used as a substrate for methanogenesis. Methanogenesis has also been detected in deep subsurface sandstone, where it is hypothesized that methanogenic consortia use organic compounds that diffuse from adjacent organic-rich shale layers.

Physiology and Biochemistry

Catabolic Pathways

Methanogens generate CH_4 during growth by four catabolic pathways: autotrophic CO_2 reduction with H_2 , formate, or secondary alcohols; methyl reduction with H_2 ; fermentation of acetate or pyruvate; and methylotrophic dismutation of methanol, methylated amines, or methylthiols. In addition, some species grow on CO and *M. acetivorans* was recently reported to grow nonmethanogenically on CO with acetate and formate as the end products. The reactions for methanogenesis are shown in Table 2. Six coenzymes serve as the principle carbon carriers in the methanogenic pathway (Figure 8). Methanofuran (MFR) is an analogue

Table 2 Reactions and free energy yields from methanogen substrates

Substrate	Reaction	ΔG^0 (kJ mol ⁻¹ CH ₄)
Hydrogen/carbon dioxide	$4\text{H}_2 + \text{HCO}_3^- \rightarrow \text{CH}_4 + 3\text{H}_2\text{O}$	-135
Formate	$4\text{HCOO}^- + 4\text{H}^+ \rightarrow \text{CH}_4 + 3\text{CO}_2 + 2\text{H}_2\text{O}$	-145
Ethanol ^a	$2\text{CH}_3\text{CH}_2\text{OH} + \text{HCO}_3^- \rightarrow 2\text{CH}_3\text{COO}^- + \text{H}^+ + \text{CH}_4 + \text{H}_2\text{O}$	-116
Hydrogen/methanol	$\text{CH}_3\text{OH} + \text{H}_2 \rightarrow \text{CH}_4 + \text{H}_2\text{O}$	-113
Methanol	$4\text{CH}_3\text{OH} \rightarrow 3\text{CH}_4 + \text{HCO}_3^- + \text{H}_2\text{O} + \text{H}^+$	-105
Trimethylamine ^b	$4\text{CH}_3\text{NH}^+ + 9\text{H}_2\text{O} \rightarrow 9\text{CH}_3 + 3\text{HCO}_3^- + 4\text{NH}_4 + 3\text{H}^+$	-76
Dimethylsulfide ^c	$2(\text{CH}_3)_2\text{S} + 3\text{H}_2\text{O} \rightarrow 3\text{CH}_4 + \text{HCO}_3^- + 2\text{H}_2\text{S} + \text{H}^+$	-49
Acetate	$\text{CH}_3\text{COO}^- + \text{H}_2\text{O} \rightarrow \text{CH}_4 + \text{HCO}_3^-$	-31
Pyruvate	$4\text{CH}_3\text{COCOOH} + 2\text{H}_2\text{O} \rightarrow 5\text{CH}_4 + 7\text{CO}_2$	-31
Carbon monoxide	$4\text{CO} + 5\text{H}_2\text{O} \rightarrow \text{CH}_4 + 3\text{HCO}_3^- + 3\text{H}^+$	-196

of molybdopterins, which occur in enzymes that catalyze similar reactions in the *Bacteria* and *Eukarya*. Tetramethanopterin (H_4MPT) is an analogue of tetrahydrofolate (H_4THF), which is also a one-carbon carrier in bacterial and eukaryal systems. Although H_4MPT was initially found to be unique to methanogens, it has since been detected in other *Archaea* and, more recently, enzymes catalyzing the methyl transfer for MFR and H_4MPT have been found to coexist with the H_4THF pathway in the CH_4 -utilizing methanotrophic *Bacteria*. The methyl carrier coenzyme M (CoM-SH), 7-mercaptoheptanoylthreonine phosphate (HS-HTP), and cofactor F_{430} are currently unique to the methanogens.

Methanogenesis from H_2 , formate, or secondary alcohols involves the sequential reduction of CO_2 with electrons generated by substrate oxidation (Figure 9(a)). The methanogenic sequence is initiated by a two-electron reduction of CO_2 and MFR by formyl-MFR dehydrogenase (a) to form formyl-MFR (Figure 10). The formyl group is then transferred to H_4MPT by formyl-MFR: H_4MPT formyltransferase (b) yielding formyl- H_4MPT . A homologue of H_4MPT , tetrahydrosarcinapterin (H_4SPT), found in *Methanosarcina* spp., differs by an additional glutamyl moiety in the substituted R group. Formyl- H_4MPT cyclization to methenyl- H_4MPT is catalyzed by N5,N10-methenyl- H_4MPT cyclohydrolase (c). N5,N10-methylene- H_4MPT dehydrogenase (d) and N5,N10-methylene- H_4MPT reductase (e) catalyze the sequential reduction of methenyl- H_4MPT by the electron carrier coenzyme F_{420} to methylene- H_4MPT and methyl- H_4MPT . The methyl group is then transferred to CoM-SH by N5-methyl- H_4MPT :CoM-SH methyltransferase (f) forming methyl-S-CoM. Methyl-CoM reductase (g) catalyzes the terminal reduction of methyl-S-CoM by two electrons from HS-HTP to CH_4 . CoM-SS-HTP is the product of the terminal reaction, which is subsequently reduced by heterodisulfide reductase to regenerate the reduced forms CoM-SH and HTP-SH.

The acetotrophic pathway for acetate catabolism proceeds by initial 'activation' of acetate by formation of acetyl coenzyme A (CoA). *Methanosarcina* spp. synthesize acetyl-CoA by sequential activities of phosphotransacetylase and acetyl kinase (Figure 9(b)). In contrast, activation of acetate to acetyl-CoA by *Methanosaeta* spp. is catalyzed in a single step by acetyl-CoA synthase. In both

Figure 9 Four overlapping methanogenic pathways found in *Methanosarcina barkeri*. All four pathways share a common step in the reduction of methyl-CoM to methane; however, they differ in the pathway used to form methyl-CoM, and in the source of the electrons used for its reduction to methane. (a) Many methanogens reduce CO_2 to methane using electrons derived from the oxidation of H_2 via the hydrogenotrophic pathway. (b) In the aceticlastic pathway, acetate is split into a methyl group and an enzyme-bound carbonyl moiety. The latter is oxidized to CO_2 to provide the electrons required for reduction of the methyl group to methane. (c) In the methylotrophic pathway, C-1 compounds such as methanol or methylamines are disproportionated to CO_2 and methane; one molecule of the C-1 compound is oxidized to provide electrons for reduction of three additional molecules to methane. (d) In the methyl reduction pathway, C-1 compounds can be reduced using electrons derived from hydrogen oxidation. Ech, ferredoxin-dependent hydrogenase; Frh, F_{420} -dependent hydrogenase; Vho, methanophenazine-dependent hydrogenase; Fpo, F_{420} dehydrogenase; CHO-MF, formyl-methanofuran; $CHO-H_4MPT$, formyl-tetrahydromethanopterin; $CH=H_4MPT$, methenyl-tetrahydromethanopterin; $CH_2=H_4MPT$, methylene-tetrahydromethanopterin; CH_3-H_4MPT , methyl-tetrahydromethanopterin; CH_3-CoM , methyl-coenzyme M; CoM, coenzyme M; CoB, coenzyme B; CoM-CoB, mixed disulfide of CoM and CoB; Meph/Meph $_2$, oxidized and reduced methanophenazine; F_{420}/F_{420H_2} , oxidized and reduced factor 420; Fd(ox)/Fd(red), oxidized and reduced ferredoxin; Ac, acetate; Ac-Pi, acetyl-phosphate; Ac-CoA, acetyl-coenzyme A. Figure 10 Methanogenic pathway in which CO_2 is sequentially reduced as coenzyme-bound intermediates to form CH_4 . Details are described in the text. Reproduced with permission from Weiss DS and Thauer RK (1993) *Cell* 72: 819–822. Cell Press.

genera, cleavage of the C–C and C–S bonds of acetyl-CoA is then catalyzed by the acetyl-CoA decarbonylase/synthase complex, yielding enzyme-bound methyl and carbonyl groups. The complex contains CO:acceptor oxidoreductase, Co- β -methylcobamide: tetrahydropterine methyltransferase, and acetyl-CoA synthase activities. The five subunit complex consists of a two-polypeptide CO-oxidizing nickel/iron-sulfur component, a two-polypeptide corrinoid/iron-sulfur component, and a single polypeptide of unknown function. The nickel/iron-sulfur component catalyzes the cleavage of acetyl-CoA, the oxidation of the bound carbonyl to CO_2 , and methyl transfer to the corrinoid/iron-sulfur component. The methyl group is sequentially transferred to H_4SPT by a currently unknown process and to HS-CoM by $\text{H}_4\text{MST:CoM-SH}$ methyltransferases. Methyl-S-CoM is reductively demethylated to CH_4 by methylreductase as previously described. The enzyme-bound carbonyl group is oxidized to CO_2 . *Methanosarcina* spp. and autotrophic methanogens growing on H_2/CO_2 synthesize acetate, presumably by reversing the direction of the acetyl-CoA decarbonylase/synthase complex in a reaction analogous to acetyl-CoA synthase in acetate-utilizing *Clostridia*.

Methylotrophic catabolism of methanol and methylated amines requires three polypeptides for the initial reaction. Methanol is catabolized by transfer of its methyl group to a corrinoid-binding protein, which is methylated by a substrate-specific methyltransferase, methanol:5-hydroxybenzimidazolyl (MT1). The methyl group is then transferred from the corrinoid protein to coenzyme HS-CoM by methylcobamide:CoM methyltransferase (MT2) (Figure 9(c)). Trimethylamine, dimethylamine, and monomethylamine each require a distinct corrinoid-binding protein, which is methylated by a substrate-specific methyltransferase. The methyl group is then transferred from the corrinoid protein to coenzyme HS-CoM by a common MT2 homologue. In contrast, catabolism of the methylthiols, dimethylsulfide, and methylmercaptopropionate is catalyzed by only two polypeptides: a corrinoid-binding protein tightly bound to a methylcobamide:CoM methyltransferase homologue of MT2. Methyl-S-CoM generated from methanol, methylated amines, and methylthiols is reduced to CH_4 in the methanogenic pathway, as has been described. A portion of the methyl groups generated from methylotrophic catabolism is oxidized in reverse sequence in a pathway identical to the CO_2 reduction pathway, after what appears to be a direct transfer of the methyl groups to H_4MPT . However,

the mechanism of this transfer is not yet known. This oxidative sequence generates electrons for the reduction of CoM-S-S-HTP in the methyl-S-CoM reductase system. Methylotrophic substrates can also be converted to methane by reduction of their methyl groups via hydrogen oxidation instead of partial oxidation of their methyl groups (Figure 9(d)).

Bioenergetics

The methanogenic *Archaea* derive their metabolic energy from autotrophic CO₂ reduction with H₂, formate, or secondary alcohols, cleavage of acetate, or methylotrophic dismutation of methanol, methylated amines, or methylthiols (Table 2). Currently, there is little evidence to convincingly support substrate-level phosphorylation. Evidence that redox reactions in the catabolic pathways are catalyzed, in part, by membrane-bound enzyme systems and are dependent upon electrochemical sodium ion or proton gradients indicates that electron transport phosphorylation is responsible for ATP synthesis. Both gradients generate ATP for metabolic energy via membrane ATP synthases. Several reactions in the methanogenic pathway are sufficiently exergonic to be coupled with energy conversion, including reduction of methyl-CoM (−29 kJ mol^{−1}) and methyl transfer from H₄MPT/H₄SPT to HS-CoM (−85 kJ mol^{−1}).

In addition, the oxidation of formyl-MF (−16 kJ mol^{−1}) during methyl oxidation in the methylotrophic pathway and CO oxidation (−20 kJ mol^{−1}) in the acetotrophic pathway are also exergonic.

During growth on H₂-CO₂ or H₂-methanol, the H₂:heterodisulfide oxidoreductase system catalyzes the H₂-dependent reduction of CoM-S-S-HTP to HS-CoM (Figure 9). Electron translocation across the membrane generates a proton gradient for ATP synthesis via an A₁A₀ ATPase. During methylotrophic growth of methanol or methylamines, heterodisulfide dehydrogenase is linked to F₄₂₀ dehydrogenase instead of hydrogenase for CoM-S-S-HTP reduction and generation of a proton gradient. Reduced F₄₂₀ is generated by methylene-H₄MPT dehydrogenase and methylene-H₄MPT reductase. A third type of heterodisulfide oxidoreductase system in the acetotrophic pathway is linked to acetyl-CoA decarboxylase via ferridoxin.

In addition to proton gradients, methanogens also use sodium ion gradients to drive endogenic reactions and generate ATP. During growth on H₂-CO₂ or acetate, vectorial Na⁺ translocation is coupled to methyl-H₄MPT:CoM-SH methyltransferase. The Na⁺ gradient generates ATP via an F₁F₀ ATPase. During growth on methanol and methylamines, a sodium ion gradient is formed by a Na⁺/H⁺ antiporter, and the methyl-H₄MPT:CoM-SH methyltransferase sodium pump is used in reverse to drive the endergonic methyl transfer from methyl-CoM to methyl-H₄MPT, for subsequent oxidation of the methyl groups.

Formyl-MFR dehydrogenase is involved in the bioenergetics of autotrophic growth on H₂-CO₂ or methylotrophic growth on methanol. During hydrogenotrophic growth, the exergonic CO₂ reduction to formyl-MF is driven by a hydrogenase-generated H⁺ or Na⁺ gradient. The reaction is reversed during CO₂ generation by methylotrophs, resulting in a net H⁺ or Na⁺ gradient.

Biosynthetic Pathways

Most methanogens assimilate carbon by CO₂ fixation or acetate uptake, and current evidence indicates that assimilation occurs via acetyl-CoA synthesis in a pathway analogous to the Ljungdahl–Wood pathway in acetotrophic clostridia. This conclusion is supported by (1) labeling studies; (2) the presence of acetyl-CoA synthase in autotrophic methanogens; and (3) the absence or partial absence of enzymes required for other routes of CO₂ fixation, including the Calvin cycle, reverse tricarboxylic acid (TCA) cycle, the serine pathway, and ribulose monophosphate cycle of the methylotrophs and the hydroxypropionate pathway of *Chloroflexus*. Acetotrophic methanogens likely utilize acetyl-CoA directly synthesized by acetate kinase and phosphotransacetylase in the catabolic acetate pathway. In the autotrophic methanogens, current evidence suggests that methyl-H₄MPT, formed by CO₂ fixation in the H₄MPT reductive pathway, likely donates a methyl group to a corrinoid protein containing an iron–sulfur center where it is subsequently transferred to HS-CoA by acetyl-CoA synthase. This pathway is a reversal of the acetotrophic pathway for acetate catabolism. During growth on methanol or methylated amines, methyl-H₄MPT, formed by direct methyl transfer to H₄MPT, is also the likely precursor for acetyl-CoA synthesis in methylotrophs.

Acetyl-CoA is reductively carboxylated by pyruvate oxidoreductase and enters the predominant biosynthetic pathways as pyruvate via an incomplete TCA. Both reductive and oxidative partial TCA cycles are detected in methanogens and their distribution among species is based on the bioenergetics of α-ketoglutarate synthesis. The oxidative incomplete TCA pathway requires a second acetyl-CoA and is restricted to acetotrophic methanogens, which readily synthesize acetyl-CoA from acetate via acetate kinase and phosphotransacetylase. In contrast, the reductive incomplete TCA pathway requires two additional reductive reactions and a reductive carboxylation to α-ketoglutarate synthesis. This pathway is commonly found in autotrophic methanogens, which have a steady reducing potential from H₂. Studies based on labeling and identification of specific enzymatic activities in selected species, thus far, indicate that biosynthesis of the aromatic aspartate, glutamate, histidine, pyruvate, and serine families of amino acids occurs by pathways similar to those described in the *Bacteria* and *Eukarya*. Genetic studies indicate that aromatic amino acids in some species are synthesized by the *de novo* via chorismate and by activation of aryl acids via the CoA thioesters indoleacetyl-CoA, phenylacetyl-CoA, and *p*-hydroxyphenylacetyl-CoA, which are then reductively carboxylated by indolepyruvate oxidoreductase to indolepyruvate, phenylpyruvate, or *p*-hydroxyphenylpyruvate, respectively. Biosynthesis of hexoses, required as precursors for cell walls and reserve polysaccharides, such as glycogen and trehalose, proceeds via gluconeogenesis from phosphoenolpyruvate. Pentoses are formed from fructose 1,6-phosphate and glyceride 3-phosphate via transketolase and transaldolase in *Methanobacterium* and *Methanococcus*. In contrast, *Methanospirillum* forms pentoses by oxidation of glucose-6-phosphate. Labeling studies in *Methanospirillum* and *Methanobacterium* indicate that pyrimidine and purines are synthesized by the expected pathways and they also

have a purine salvage pathway. The polar core lipids, which include diphytanyl glycerol ethers and diphytanyl diglycerol tetraethers, are synthesized via the mevalonate pathway for isoprenoids.

Molecular Genetics

Genome Structure

The methanogens have a single circular chromosome that ranges from 1.6×10^6 to 5.7×10^6 bp in size. The percentage guanosine + cytosine (%GC) ranges from 23% to 62% and high %GC content is not always associated with high growth temperatures. Transposable elements are detected in all methanogen genomes. A three-way comparison between *M. acetivorans*, *Methanosarcina barkeri*, and *Methanosarcina mazei* reveals that genomes are well conserved with respect to the region proximal to the origin of replication, but the second half of the genomes most distant from the origin are disordered and marked by increased transposase frequency and a decrease in gene density and conserved colocalization (synteny). The apparent genome plasticity might contribute to these species' ability to adapt to a broad range of environments as a result of genome elongation and enrichment for favorable phenotypes. CRISPRs (clustered regularly interspaced short palindromic repeats), which can cause large-scale rearrangements, and all four known CRISPR-associated, or *cas*, genes have been detected in methanogen genomes, but they do not appear to be associated with large-scale DNA rearrangements.

Extrachromosomal DNA has been detected in methanogens in the form of large extrachromosomal elements, plasmids, viruses, and virus-like particles. At this time, two large extrachromosomal elements have been detected in *Methanocaldococcus jannaschii* (58.4 kb) and *M. barkeri* (36 kb) and 12 smaller plasmids, ranging in size from 4.4 to 20 kb, have been detected in four genera of the methanogenic *Archaea*. The large extrachromosomal element in *M. jannaschii* encodes a putative minichromosome maintenance (MCM) helicase and the element in *M. barkeri* encodes a homologue of the DNA replication initiation protein, Cdc6, in a region of highly repetitive sequence, which suggests replication of the large extrachromosomal elements is synchronous with cell division. In contrast homologues of site-specific recombinase and plasmid DNA replication initiator protein RepA detected in *M. acetivorans* suggests that this plasmid replicates by a rolling circle mechanism associated with many bacterial plasmids and phage. Other open reading frames annotated in methanogen plasmids include a type II DNA restriction–modification system, glycosylase transferase, and recombinases. However, genes involved in central metabolism have not yet been detected and the functions of the most methanogen plasmids are cryptic at this time. Lytic viruses have been detected in three strains of *Methanothermobacter* and one strain of *Methanobrevibacter smithii*. These viruses show a varying range of host specificities. A temperate virus-like particle has been isolated that can integrate into the chromosome of *Methanococcus voltae*.

In contrast to the similarities of DNA structure in methanogenic *Archaea* and *Bacteria*, DNA-modifying proteins in the methanogens share features common to both the *Bacteria* and *Eukarya* (Table 3). All cells must package their genomic DNA within the limited space of the cells. Although the *Bacteria* do not appear to have a conserved mechanism for DNA packaging, all *Eukarya* and some *Archaea* (one crenarchaeon and all Euryarchaeota) chromosomal DNAs are compacted by histones into defined structures called nucleosomes, which are further assembled to form chromatin. Methanogen histones form a structural motif called a histone fold, but lack N- and C-terminal sequences associated with higher order nucleosome polymerization and undergo modification in eukaryotes. Unlike the four histones in eukaryotes, methanogens typically encode 1–6 histones. Interestingly, *Methanosarcina* spp., which have the largest genomes, only encode one histone and it is not clear how this affects dimer polymerization. Archaeal histone-like proteins increase the melting temperature of linear DNA *in vitro* by as much as 25 °C and likely protect DNA from heat denaturation *in vivo*. Reverse gyrase, also detected in *Methanothermobacter feravidus*, may contribute to heat resistance of DNA by creating stable positive supercoils in inter-histone regions. Histone-like proteins isolated from mesophilic *Methanosarcina* species cause

Table 3 Molecular features of three phylogenetic domains

Feature	Eukarya	Bacteria	Archaea
Genome	Multiple linear	Single circular ^a	Single circular ^a
Chromatin	Histone-mediated	No conserved mechanism	Histone-mediated
Extrachromosomal DNA	Plasmids, viruses, IS units	Plasmids, viruses, IS units	Plasmids, viruses, IS units
DNA polymerase	Families A ^b , B, and X	Families A, B, and C	Families B and X
RNA polymerase	Three classes, complex	One class $\beta\beta'\alpha_2\sigma$	One class, complex ^c
Gene structure	Single gene	Multiple gene operon	Multiple gene operon
Transcription promoter	TATA box	–35/–10 sequence	TATA box
Transcription terminator	AAUAAA sequence	Intrinsic, σ -dependent	Intrinsic, oligo T
Ribosomal RNA	28S–5.8S/18S	23S–5S/16S	23S–5S/16S
Translation initiation	5' cap	Ribosomal-binding site	Ribosomal-binding site
Initiator transfer RNA	Methionine	Formylmethionine	Methionine

^bMitochondrial.

^cAB'B'C based on homology to eukaryal RNA polymerase II.

concentration-dependent inhibition or stimulation of gene transcriptions *in vitro*, which suggests that they might also have a role in gene regulation. Direct evidence that *M. jannaschii* histones does not have posttranslational modifications indicates that gene regulation by histone modification is unlikely, but this does not rule out the possibility that different sequence affinities might regulate genes by selective proximity of nucleosomes to regulatory regions of DNA.

DNA Replication, Repair, Modification, and Metabolism

Unlike replication in the *Bacteria*, which starts at a single origin, *in silico* analysis indicates there are up to three origins in some species of methanogens. Multiple origins have been experimentally determined in the *Crenarchaea*, which suggests that some species of methanogenic *Archaea* may also have multiple origins. At least one of the origins lies immediately upstream of genes encoding homologues of the eukaryal DNA replication initiation proteins Orc and Cdc6. The proximity of the replication factors to the origin suggests that the methanogenic *Archaea* use a bacterial-like mode of replication, but with eukarya-like machinery. DNA replication proteins in methanogens are similar to those of other members of the euryarchaeal kingdom and most similar to eukaryal enzymes. Studies on the replication machinery of a number of methanogenic *Archaea* show that most have homologues of the eukaryotic initiation proteins Orc/Cdc6, which are thought to function in origin recognition and helicase loading. All methanogenic *Archaea* also contain at least one homologue of the replicative helicase, MCM. The replicative machinery also includes the proteins needed for the elongation phase including primase, DNA polymerases (B- and D-type), the PCNA processivity factor and its loader RFC, the GINS complex, thought to function in coordination of leading and lagging strand replication, and ligase, Fen1 and RNase H needed for Okazaki fragment maturation.

DNA repair mechanisms have also been identified in methanogens. Annotation of genome sequences reveals putative genes for alkyltransferase, base-excision repair, photoreactivation, nucleotide excision repair, *trans*-lesion synthesis, mismatch repair, and homologous recombination among species of the methanogenic *Archaea*. A photoreactivation system in *Methanothermobacter thermoautotrophicus* is mediated by class II photolyase with homology to metazoan photolyases. Homologues of putative DNA include eukaryal repair proteins RAD2, RAD25, and RAD51; and bacterial DNA repair proteins uvrABC, RadA, mutL, and mutS. Although our understanding of DNA repair in the *Bacteria* and *Eukarya* is well advanced, there has been comparatively little functional analyses of these processes in the methanogenic *Archaea* at the present time.

Gene Structure and Transcription

The organization of methanogenic genes in tightly linked clusters is similar to the operon configuration found in the *Bacteria*. As in the *Bacteria*, the archaeal operons are transcribed from an upstream promoter into polycistronic RNAs such that individual mRNA molecules encode multiple genes and transcription and translation are coupled. However, archaeal genes are transcribed by a multicomponent RNA polymerase that is structurally homologous to eukaryal RNA polymerase and recognizes a promoter with high sequence homology to the consensus TATA motif found in eukaryal promoters and B recognition element (BRE) immediately upstream. Unlike the variable upstream distance of eukaryal promoters, the archaeal promoter element is located at a consistent distance, approximately 20–30 bp upstream from the transcription initiation site, a range similar to the conserved –35 bp region observed in the *Bacteria*. Site-directed deletion studies conducted with methanogenic *Archaea* by *in vitro* techniques indicate that efficient transcription and start-site selection is dependent upon a TATA promoter. This arrangement closely resembles the core structure of promoters recognized by RNA polymerase II (RNAP II) in the *Eukarya*. Purified archaeal RNAPs from *M. thermoautotrophicus* and *M. voltae* fail to initiate site-specific transcription without the addition of a protein that binds to the TATA promoter (TBP) and transcription factor B (TFB). Yeast and human TATA-binding proteins can substitute for TBP in a *Methanococcus*-derived archaeal cell-free transcription system, indicating that they are functionally homologous. An additional gene that has sequence similarity to a eukarya-like transcription factor E (TFE) has also been identified in the methanogenic *Archaea*. Site-specific transcription initiation in the *Archaea* is analogous to that in the *Eukarya*. The mechanism involves binding of the TBP to the archaeal TATA box, stabilization of the complex by association of TFB with TBP and interaction with the BRE, and recruitment of the RNAP TFE facilitates binding of TFB to RNAP and further stabilizes the initiation complex by closing the RNAP clamp on the DNA strand.

Mechanisms of transcriptional regulation in some highly regulated genes have been reported. Regulatory protein Ptr2 in *M. jannaschii*, an archaeal homologue of the bacterial leucine-responsive regulatory protein Lrp, is a transcriptional activator for expression of ferridoxin A and rubredoxin 2. However, unlike bacterial activators that interact with RNAP, Ptr2 activates transcription by recruiting transcription factor. Negative regulators have also been described in the methanogens. TrpY is an allosteric effector that both autoregulates itself and regulates transcription of the tryptophan biosynthesis operon. TrpY forms a dimer that inhibits TrpY expression by blocking RNAP recruitment. When tryptophan binds to TrpY a conformational change increases its affinity for an adjacent, divergent operator for the tryptophane encoding operon (*trp*), thereby competing with TBP binding to the promoter. NrpR regulates nitrogen fixation by repressing the operon encoding nitrogenase (*nif*) during growth with alternative nitrogen sources ammonia or alanine. In the absence of ammonia or alanine, an indicator of intracellular nitrogen level, 2-oxyglutarate, binds to NrpR and reduces its affinity for the *nif* operator, thereby derepressing transcription of the *nif* operon. Regulators involving the 5' untranslated region (5'-UTR) of the mRNA have also been reported in the methanogens. A systematic approach using transcriptomic modeling of *M. maripaludis* under different growth condition in a chemostat identified two novel transcription factors in the regulation of phosphate-dependent repression of formate dehydrogenase.

A 113 nucleotide 5'-UTR upstream of an RNA helicase in the Antarctic species *Methanococcoides burtonii* contains bacteria-like regulatory elements that appear to be involved in cold adaptation. Long 5'-UTRs associated with methanol methyltransferase and carbon monoxide dehalogenase in *Methanosarcina* spp. have also been shown to be involved in regulation. Although the mechanisms of regulation have not been determined, five genes designated msrABCDE – identified by deletion analysis – are involved in repression or induction of methanol methyltransferase isozymes. In the case of carbon monoxide dehalogenase, expression is regulated in response to substrate by at least two mechanisms: differential transcription initiation and early elongation termination near the 3' end of a 371-bp leader sequence. Genes encoding three distinct TBPs have been detected in the *M. acetivorans* genome, which raises the possibility that gene regulation is mediated by differential TBP–promoter pairing. Only TBP-1 is expressed during growth of *M. acetivorans*, but this does negate the possibility that the different TBPs might be differentially expressed under different growth conditions, such as a response to stress. This possibility is supported by evidence of differential TBP–promoter pairing in the closely related halophilic *Euryarchaeota*. Generally, transcription is terminated following an inverted repeat sequence located downstream of methanogen genes. Transcription termination sites are similar to the ρ -independent terminators in the *Bacteria*, and likely form a stem-loop secondary structure to mediate termination. A second type of transcription terminator, which consists of a single or several tandemly arranged oligo-T sequences, is found in hyperthermophilic methanogens. The occurrence of this terminator in hyperthermophiles suggests that the stem-loop structures characteristic of σ -independent promoters may be unstable at higher growth temperatures.

RNA Structure and Translation

The stable RNAs transcribed by methanogen genes have been investigated in some detail. Methanogen ribosomes resemble bacterial ribosomes. They are composed of two protein subunits of 30S and 50S and three rRNA components of 23S, 16S, and 5S, which, assembled, yield a ribosome of 70S. Archaeal and bacterial ribosomal proteins are functionally homologous and can be interchanged to create an active ribosome *in vitro*. Genes encoding rRNA are arranged in the order 16S-23S-5S and the number of operon copies varies in number from 1 to 4. The organization and order of genes encoding methanogen ribosomal proteins also resembles that found in the *Bacteria*. Methanogen transfer RNAs (tRNAs) contain the sequence 1-methyl ψ CG substituted for the sequence T ψ CG, typically found in the arm of bacterial and eukaryal tRNAs. Introns have been detected in genes encoding tRNA. Several methanogenic *Archaea* lack cysteinyl-tRNA synthetase. In these cases, a class II-type O-phosphoseryl-tRNA synthetase specifically forms Sep-tRNA^{Cys}, which is then converted to Cys-tRNA^{Cys} by Sep-tRNA:CystRNA synthase. Several methanogenic *Archaea* also synthesize two nonstandard amino acids: selenocysteine, found also in *Bacteria* and animals, and pyrrolysine, which is thus far unique to methanogenic *Archaea* with genes encoding dimethylamine or trimethylamine methyltransferases. Both selenocysteine and pyrrolysine are encoded by the RNA stop codons UGA and UAG, respectively. However, unlike selenocysteine that is synthesized on the charged tRNA, pyrrolysine is charged onto a pyrrolysine-specific tRNA.

Some methanogen mRNAs have poly-A⁺ tails, but, as in the *Bacteria*, they average only 12 bases in length. Protein-encoding genes employ the same genetic code as *Bacteria* and *Eukarya*, and codon preferences reflect the overall base composition of the genome and the level of gene expression. The codon ATG is frequently used as an initiation codon as well as GTG and TGG. A ribosomal-binding site located upstream of structural genes, when transcribed, is complementary to the 3' terminal sequence of methanogen 16S rRNA. Compared with *Bacteria* and *Eukarya*, there is little information on the mechanisms of translation based on biochemical experimentation. Computational analyses of methanogen genomes have identified six putative initiation factors, two elongation factors, and one release factor that are most similar to eukaryal homologues. Inteins have been identified by genomic sequencing of *M. jannaschii*, which suggests that protein splicing occurs in methanogens. RNA processing by endonucleolytic cleavage 12–16 nucleotides upstream of the translation start site of 30 protein-coding genes was identified in *Methanocaldococcus jannaschii*. In addition, evidence has been found for phosphorylation of proteins at a tyrosine residue, which is a mechanism of posttranslational control in the *Bacteria* and *Eukarya*.

Genomics and Gene

Function analysis

The genomes of strains from over 20 methanogenic genera have been completely sequenced and annotated. In general, similar genes are found for the CO₂-reducing catabolic pathways in all four genomes. Genes encoding multiple methyltransferases and acetyl-CoA decarbonylase/synthases are found only in the genomes of *Methanosarcina* spp., which is consistent with the ability of this species to also grow by methylotrophic and acetoclastic pathways. The large genome size of *Methanosarcina* spp. likely reflects these species' ability to use a greater range of substrates, adapt to a broader range of environments, and form complex multicellular structures compared with the more limited capabilities of the hydrogen-utilizing species. In contrast, the hyperthermophiles are more 'minimalist' exhibiting a paucity of genes encoding proteins for signaling and gene regulation, *grpE*–*dnaJ*–*dnaK* heat-shock operon, proteasome–chaperonin, several DNA repair proteins, DNA helicases, nitrogenase subunits, ribonucleotide reductase, and proteases. Despite their sensitivity to oxygen, superoxide dismutase and catalase have been identified in methanogen genomes. Superoxide dismutase and catalase activities have been confirmed and characterized in methanogens, and genes encoding both enzymes are transcriptionally upregulated in *M. barkeri* upon oxidative stress. Interestingly, a putative cytochrome *d* has been identified in *Methanosarcina* genomes, but its role has not been determined. Overall, the majority of archaeal open reading frames with similarity to bacterial sequences include genes for small molecule biosynthesis, intermediary metabolism, transport, nitrogen

fixation, and regulatory functions. Archaeal open reading frames with similarity to eukaryal sequences include genes for DNA metabolism, transcription, and translation. The presence of Cdc6 homologues and histones suggests that DNA replication initiation and chromosome packaging is eukaryal, but detection of cell division gene *ftsZ* suggests that bacteria-type cell division occurs. Additional unique features include an archaeal B-type DNA polymerase with two subunits, putative RNAP A' subunits that suggest possibility of additional mechanisms for gene selection, and two introns in the same tRNA^{Pro} (CCC) gene that establishes a new precedent. A genomic-scale metabolic model was created for *M. acetivorans* that identified key knowledge gaps and accurately predicted wild-type phenotypes and knockout lethality as a tool for hypothesis testing by genetic analyses.

The availability of genome sequences of methanogens and current activities to sequence others make the development of archaeal gene-transfer systems essential for confirmation of gene function. Two gene-transfer systems have been developed for species of *Methanococcus* and *Methanosarcina*. Both systems utilize hybrid shuttle vectors derived from native archaeal plasmids. Since plasmids occur in low copy number in the methanogens, the DNA to be transferred is ligated into the vector, which is then amplified in *E. coli* with ampicillin as a selectable marker. The modified plasmid is then transferred into the methanogen using transformation methods that employ either cells made competent for DNA uptake by polyethylene glycol treatment (*Methanococcus* sp.) or uptake of DNA embedded in liposomes (*Methanosarcina* spp.). A second selectable marker in the plasmid, such as *pac* (puromycin acetyl transferase) controlled by a highly expressed methanogen promoter *mcr* (methyl CoM reductase), provides selection in the methanogen. Both autonomously replicating plasmids for introducing specific phenotypes and integration plasmids for disrupting genes by homologous recombination have been designed. These systems are highly efficient, yielding 10^7 – 10^9 transformants per μg DNA. Methods for gene disruption based on homologous recombination and transposon-mediated mutagenesis, gene reporters for expression analysis, and protein overexpression have also been developed. One current limitation is the limited number of selectable and phenotypic markers that are currently available. This has been addressed by the development of a 'markerless' system in which the genetic marker is removed by homologous recombination after selection. A transducing phage has been isolated from *M. thermoautotrophicus*, but it is not currently useful for gene transfer because of its limited burst size (~ 6 /cell). Conjugation has not been observed in methanogens. Although gene-transfer systems are somewhat limited at this time, development of new and more sophisticated systems is ongoing.

Conclusion

The methanogenic *Archaea* have a pivotal role in the global carbon cycle by complementing aerobic processes that ultimately lead to the oxidation of organic carbon to CO₂. However, a steady increase in the levels of atmospheric CH₄ that has coincided with the increase in the human population is a cause for concern, since CH₄ is a greenhouse gas. Methane's contribution to global warming results from its high infrared absorbance and its role in complex chemical reactions in the stratosphere that affect the levels of ozone. Increased waste disposal activities, such as landfills, are a significant source of atmospheric CH₄. Another significant source results from agricultural activities, such as the increased use of domesticated ruminants for production of meat and dairy products and the increased development of rice paddies. Understanding the properties of methanogens and the roles they have in the global carbon cycle will have important implications in addressing the issue of global warming as the human population increases. The ability of geological hydrogen-utilizing CO₂-reducing methanogens to serve as primary producers of reduced carbon compounds in deep subsurface bedrock and submarine vents has significant implications also in astrobiology and the potential for extraterrestrial life.

The application of methanogens in biotechnology has been largely limited to waste management, which is often coupled to limited biogas production. Although the petroleum crisis of the 1970s led to an interest in methanogenic biogas production by fermentation of sources ranging from agricultural products to marine kelp, cost-effective technologies were never fully developed as interest waned with the drop in petroleum prices. Recent rises in petroleum prices and international concern about global warming have renewed interest in alternative energy sources. Methanogenic biogas is an attractive energy source for applications such as heating and electric generation plants as it requires minimal treatment and can be distributed in current infrastructures used for natural gas. Unlike petroleum, biogas is generated from organic waste and CO₂ released from combustion of biogas does not cause a net increase of greenhouse gases into the atmosphere. Similarities in the DNA expression machinery of mesophilic methanogens and *Eukarya* combined with recent advances in methanogen genetic systems provides a potential platform for functional analyses of mammalian gene and proteins. Other potential applications for methanogens include the production of novel pharmaceuticals, corrinoids, and thermo-stable enzymes. To date, methanogens have yielded only a few restriction endonucleases as commercial products. However, significant advances in our understanding of the physiology and biochemistry of methanogens over the past two decades, combined with the recent developments in gene transfer systems and advances in genome sequencing, make the application of methanogens for biotechnology more likely in the near future.

Glossary

cause A condition that is necessary in the circumstances for bringing about an event.

model An idealized, usually causal, mechanism or collection of mechanisms that account for a biological outcome.

scientific method A collection of general principles of scientific inquiry, test, and evaluation.

strong inference A systematic attempt to devise mutually exhaustive alternative hypotheses and subject them to crucial experimental tests.

theory Generally, a collection of related principles that explain a domain.

Abbreviations

BSE	bovine spongiform encephalopathy
CJD	Creutzfeldt-Jakob disease
IPTG	isopropylthiogalactoside
ONPF	<i>o</i> -nitrophenyl-fucoside
PrP	prion protein
PrP ^c	cellular PrP
PrP ^{sc}	scrapie PrP
TSE	transmissible spongiform encephalopathy

Defining Statement

Philosophy of method is a branch of the philosophy of science that investigates scientific methodology. Though 'scientific method' is largely implicit in microbiology, microbiologists do implement a number of methods of scientific inquiry that have been analyzed by philosophers, such as the methods of difference and comparative experimentation. In addition, these methods are put into practice against a backdrop of more general philosophical assumptions concerning scientific progress, scientific realism, scientific inference, and the nature of empirical evidence. The philosophy of method is best described using particular microbiological examples illustrating the application of specific methods of experimental inquiry.

Scientific Method in General

The search for a method that would articulate and codify the principles of scientific inquiry has a long history. Philosophers, in particular, have proposed a number of different approaches to scientific method, beginning with Aristotle. In more modern times, Descartes and Francis Bacon wrote on the subject, but the study of scientific method received its most systematic treatments in the work of the nineteenth-century philosophers and scientists William Whewell, Stanley Jevons, and John Stuart Mill. It was the last who forcefully re-presented the methods of agreement, difference, concomitant variation, and other methods that continue to have an influence among contemporary philosophers. Later in this article, some of the more current positions of such philosophers as Karl Popper and Thomas Kuhn will also be cited as contributing in important ways to this subject.

Though some philosophers studying scientific method, such as Francis Bacon, hoped to furnish a method of 'discovery', the majority of philosophical thinking in this area has tended to follow Popper's view that states

The initial stage, the act of conceiving or inventing a theory, seems to me neither to call for logical analysis or be susceptible of it. The question how it happens that a new idea occurs to a man – whether it is a musical theme, a dramatic conflict, or a scientific theory – may be of great interest to empirical psychology; but it is irrelevant to the logical analysis of scientific knowledge. The latter is concerned not with *questions of fact* but only with questions of *justification* or *validity*.

This view of Popper's has come under attack by a number of recent philosophers and artificial intelligence theorists. These proponents of a logic of scientific discovery have been able to develop discovery programs in a number of domains, including organic chemistry and mathematics, and active research in this area is continuing. Advances in this area are quite technical and

This article is a reprint of K.F. Schaffner, Methods, Philosophy of, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 48–57.

typically domain specific, and, thus, it will not be possible in the context of the present article to discuss in any detail these various attempts to develop a logic of discovery; this selection will primarily be concerned with the logic of testing and of proof.

It should be noted that 'scientific method' has been largely 'implicit' in the writings of microbiologists. There are some occasional reflections on methodological issues, for example, Koch's development of his 'postulates' for assessing the causation of disease by a bacteriological agent and Peter Duesberg's recent appeals to methodological issues in connection with the cause(s) of HIV disease. Another interesting methodological debate is the recent controversy about the causative agent – putatively a prion – of the spongiform encephalopathies, such as 'mad cow disease'. Though these explicit debates are the exception, microbiologists do put into practice various philosophies of method, and it is the function of the present article to make explicit what figures in a largely silent way in microbiology.

Scientific Method in Biology; Objective Truth and Scientific Progress

Theory and Experiment in Physics Compared and Contrasted with Biology

Biology in general, and microbiology in particular, shares a number of common methodological assumptions with all the natural sciences, including the physical sciences. The life sciences, however, also possess some special methodological features that will be useful to distinguish between them. Because each of the natural sciences seeks reliable general knowledge, the methods mentioned briefly in 'Scientific method in general', such as the methods of agreement and difference, are widely employed in the life and nonlife sciences. These methods can be thought of as attempting to discern the causal structure of the world, and, in their application, scientists endeavor to identify possible confounding factors that can lead to spurious inferences about causes and effects. Thus, all natural scientists attempt to control for interfering and extraneous factors, frequently by setting up a control comparison or a control group. Such controls are a direct implementation of what Mill termed the method of difference and Claude Bernard the method of comparative experimentation, which will be reviewed in some detail in 'Specific but philosophically general methods of experimental inquiry'.

In the biological sciences, including microbiology, some added complexity is frequently encountered due to biological diversity and the number of systems that strongly interact in living organisms. It is the backdrop of evolutionary theory that allows one to understand why there can be both extensive and subtle variation in organisms and mechanisms, as well as why there may be narrowly defined precise mechanisms that are (nearly) biologically universal, such as the genetic code. Variations due to meiosis, mutation, and genetic drift, for example, predict that extensive variation should occur most frequently in evolving populations where strong selection pressures toward precise and universal mechanisms are not present. Alternatively, where variations would almost certainly be lethal, there exist strong pressures toward the fixation of (nearly) universal mechanisms. Thus, evolutionary theory, at a very general level, explains some of the specific and general features of other theories and models in microbiology.

Because broad and subtle variations may be encountered in microbiology, special attention frequently needs to be given to ensuring the (near) identity of the organisms under investigation, except for those differences that are the focus of the scientist's inquiry. Accordingly, the development of special strains of organisms and the identification and classification of populations (and subpopulations) assume an urgency that can be frequently ignored in the physical sciences, where, for example, all electrons are identical. It is in connection with the satisfaction of these urgent needs that the development of the techniques of pure culture becomes so vitally important.

Organism and subsystem variation do not only influence the experimental arena, but also figure in what constitutes the biological analogue of 'theory'. Genetic and environmentally produced variation frequently results in the need of biologists (and microbiologists) to focus on 'model' organisms and on prototypical systems, which are highlighted against a backdrop of similar but different organisms and mechanisms. Biologists, thus, often find themselves practicing what a 1985 National Academy of Sciences report called 'many-many modeling' in a complex 'biomatrix'. The report, which re-presented the results of a series of workshops directed by H. Morowitz, introduced a notion of the 'matrix' of biomedical knowledge: "The workshops demonstrated that the results of biomedical research can be viewed as contribution to a complex body, or matrix, of interrelated biological knowledge built from studies of many kinds of organisms, biological preparations, and biological processes at various levels." From within this multidimensional matrix, many-many modeling occurs, in which analogous features at various levels of aggregation are related to each other across various taxa. The report notes: "An investigator considers some problem of interest – a disease process, some normal physiological function, or any other aspect of biology or medicine. The problem is analyzed into its component parts, and for each part and at each level, the matrix of biological knowledge is searched for analogous phenomena.... Although it is possible to view the processes involved in interpreting data in the language of one-to-one modeling, the investigator is actually modeling back and forth onto the matrix of biological knowledge."

Method and Scientific Progress

P. Collard, in his historical monograph on the development of microbiology, distinguished four historical eras. The period of 'speculation' comprised the epoch from about 5000 BC until the work of the microscopist Leeuwenhoek around 1675 ushered in the era of 'observation'. Beginning in the mid-nineteenth century, the era of 'cultivation' began with Pasteur's studies of fermentation and Koch's development of pure culture methods employing solid media. Collard suggests that the modern physiological era, which is dominated by the elucidation of bacteriological and biochemical mechanisms, commenced about 1900. Implicit in Collard's chronology is the inference that the more recent methodologies are more scientifically sound and objective, in contrast to the earlier, more speculative inquiries in microbiology.

It may initially appear odd to scientifically trained microbiologists to even raise the question of whether there is any 'objective truth' in science. Over the past 25 years or so, however, serious questions have been raised about the nature of scientific 'truth' and 'progress' by Kuhn in his influential work, some philosophers of science (e.g., Feyerabend), and several sociologists of science (e.g., Latour and Woolgar), and a brief discussion of these issues may be helpful.

Truth and Progress in Science

Throughout this century, philosophers of science have engaged in vigorous disputes about the nature of scientific truth. An examination of the history of science in general, and microbiology in particular, would lead one to the conclusion that there have existed many 'good' scientific theories that have not survived to the present day. Kuhn's characterization of scientific revolutions provides a superb (if ultimately misleading) introduction to examples of these discarded theories. Such theories have gone through the stages of discovery, development, acceptance, rejection, and extinction. Further examination of extinct theories, however, would show that they possessed a number of beneficial consequences for science.

Incorrect and literally falsified theories have several explanatory functions, and have systematized data, stimulated further inquiry, and led to a number of important practical consequences. For example, the false Ptolemaic theory of astronomy was extraordinarily useful in predicting celestial phenomena and served as the basis for oceanic navigation for hundreds of years. Newtonian mechanics and gravitational theory, which is incorrect from an Einsteinian and quantum mechanical perspective, similarly served both to intelligibilize the world and to guide its industrialization. In the biological sciences, the false evolutionary theory of Lamarck systematized and explained significant amounts of species data, and in microbiology, Pasteur's false nutrient depletion theory of the immune response, nonetheless, served as the background for the development of the anthrax vaccine. Such examples lead one toward what has been termed an 'instrumentalistic' analysis of scientific theories (or hypotheses).

The basic idea behind such a position is to view theories and hypotheses as 'tools' and not as purportedly true descriptions of the world. For a thoroughgoing instrumentalist, the primary function of scientific generalizations is to systematize known data, to predict new observational phenomena, and to stimulate further experimental inquiry. Such an approach bears strong analogies to the 'constructivist' program of several sociologists of science, such as Latour and Woolgar, who conceive of many biomedical entities (e.g., neuroendocrine releasing factors) as being 'constructed' rather than as 'discovered'. To constructivists, such putatively 'real' microbiological substances are actually 'constructed socially' (as conceptualized entities), as part of a complex give-and-take among laboratory machine readings and discourse among laboratory scientists.

Though such positions as Kuhnian relativism, instrumentalism, and social constructivism are *prima facie* attractive, they are inconsistent with other features of scientific inquiry. The relation of scientific theory to 'observations' in the laboratory is exceedingly complex. In spite of the weblike connections between theoretical postulation and laboratory experiments, however, multiple empirical constraints on theoretical speculations generate a stability and 'stubbornness' of both data and theory, to use Galison's terms. For example, scientists view the distinction between what they term 'direct' and 'indirect' evidence as important. Even though, as shall be seen in the following, the distinction is relative, it is, nonetheless, significant to note that scientists 'behave' as if the distinction is important, and that 'direct evidence' would seem to support a more 'realistic' analysis of scientific theories (or hypotheses). A realistic type of alternative to the instrumentalist position would characterize scientific theories as 'candidates' for 'true' descriptions of the world. Though not denying the importance of theories' more instrumentalistic functions, such as prediction and fertility, the realist views these features as partial indications of a theory's 'truth'. The history of recent philosophy of science and the more general discipline of 'science studies' has seen an oscillation between these realist and instrumentalist positions, as well as the development of some interesting variants of these positions. The relativist reviews have been strongly criticized, especially by realism-defending scientists, the give-and-take of which has been described as the 1990s 'science wars'. This, however, is a subject that cannot be pursued within the limitations of this article.

Suffice it to say that, in spite of the variation in positions that scientists and philosophers of science have taken about the nature of ultimate scientific truth, these varying positions do not disagree about the need to report accurately and faithfully what the scientist has observed or reasoned to in his or her investigations.

Specific but Philosophically General Methods of Experimental Inquiry

This section provides a more systematic and in-depth review of the classical methods of experimental inquiry that were very briefly introduced in 'Scientific method in general'. It begins with John Stuart Mill's characterization of these experimental methods, since Mill's analysis is 'provisionally' adequate for our purposes and is also well known.

'Mill's' Methods

Mill's first experimental method is known as the 'method of agreement'. This was as follows:

If two or more instances of the phenomenon under investigation have only one circumstance in common, the circumstance in which alone all the instances agree, is the cause (or effect) of the given phenomenon.

It should immediately be pointed out that this method is most difficult to satisfy in microbiological inquiry because of the complexity of organisms. To vary every relevant character save one is largely unrealizable, though it may occasionally be done in very narrowly circumscribed investigations in molecular biology, for example, in genetic codon analysis.

The applicability of the method of agreement is also suspect in complex biological organisms for two other general reasons, originally pointed out by Mill in his *System of Logic*. These general reasons were referred to by Mill as the 'plurality of causes' and the 'intermixture of effects'. In the former, Mill noted that in those complex cases where the same consequence could be the result of different jointly sufficient antecedents, the method of agreement yielded 'uncertain' conclusions. In complex and adaptable biological organisms, such a situation is often likely. The problem of the 'intermixture of effects' produced even greater difficulties for the method of agreement. This occurred in cases where effects were 'intermixed', that is, either they were not separable into clearly defined components, or the result was emergent and incalculable on the basis of the causal components. As examples of these two species of the intermixture of effects, Mill cited the vector addition of forces in mechanics and the production of water from oxygen and hydrogen. Mill also believed that biological properties were emergent with respect to the physicochemical, with attendant difficulties. Suffice it for now to note that the method of agreement possesses serious imperfections in its application to complex circumstances, as are found in biological organisms.

Mill's methods also include, besides the better known method of agreement and the method of difference, the method of residues and the method of concomitant variations. The latter, according to Mill, may be stated in canonical form as follows:

Whatever phenomenon varies in any manner whenever another phenomenon varies in some particular manner, is either a cause or an effect of that phenomenon, or is connected with it through some fact of causation.

This method has important uses in biology and medicine, and an illustration of it will be considered in the following section on specific implementation of the methods. Again, as in the case of the method of agreement, the complexity of biological organisms makes a simple and straightforward application of the method of concomitant variations uncertain. When attempting to determine a major causal role which, say, an entity plays in a system, a simple recording of concomitant variations is almost always insufficient.

The method of residues is likewise suspect in its simple application to biological and microbiological causation. This method, in which one "subduct[s] from any phenomenon such part as is known by previous inductions to be the effect of certain antecedents", and considers "the residue of the phenomenon... [to be] the effect of the remaining antecedents", is similarly difficult to apply in complex systems in which the interfering residues are likely to be very large, both in number and in their interactions.

The method of difference supplemented in a number of cases with a statistical interpretation, which bears certain analogies to Mill's methods of concomitant variation, is often the most appropriate method of experimental inquiry to establish empirically and directly scientific claims. The method of difference was stated by Mill in the following manner:

If an instance in which the phenomenon under investigation occurs, and an instance in which it does not occur, have every circumstance in common save one, that one occurring only in the former, the circumstance in which alone the two instances differ is the effect or the cause, or an indispensable part of the cause of the phenomenon.

The application of the method of difference, like the other methods, is not automatic in any experimental situation and, as has been observed by a number of thinkers, 'presumes' an analysis of the situation into all relevant factors that can be examined one at a time.

This rather demanding requirement can be ameliorated in a way that is reasonably faithful to Mill's approach by following some suggestions of the great nineteenth-century physiologist and philosopher of method, Claude Bernard. In his influential monograph *An Introduction to the Study of Experimental Medicine*, Bernard noted that these presumptions of an antecedent analysis of the experimental situation and the ability to examine factors one at a time were not necessarily valid in experimental medicine, and he urged that the method of difference be further distinguished into (1) the method of 'counterproof' and (2) the method of 'comparative experimentation'. According to Bernard, in the method of counterproof, one assumes that a complete analysis of an experimental situation has been made, that is, all complicating and interfering factors have been identified and controlled. Subsequently, one eliminates the suspected cause and determines if the effect in which one is interested persists. Like Karl Popper in the twentieth century, Bernard believed that experimental medical investigators avoided counterproof as a method, since they feared attempts to disprove their own favored hypotheses. Bernard defended a strong contrary position and maintained that counterproof was essential to avoid elevating coincidences into confirmed hypotheses. He argued, however, that those entities that fell into the province of biology and medicine were so complex that any attempt to specify all of the causal antecedents of an effect was completely unrealistic. As a remedy for this problem, he urged the consideration of 'comparative experimentation':

Physiological phenomena are so complex that we could never experiment at all rigorously on living animals if we necessarily had to define all the other changes we might cause in the organism on which we were operating. But fortunately it is enough for us completely to isolate the one phenomenon on which our studies are brought to bear, separating it by means of comparative experimentation from all surrounding complications. Comparative experimentation reaches this goal by adding to a similar organism, used for comparison, all our experimental changes save one, the very one which we intend to disengage.

Bernard referred to comparative experimentation as 'the true foundation of experimental medicine'.

Strong Inference

The use of counterproof, crucial experiments, and comparative experimentation finds unified application in what J. R. Platt termed 'strong inference'. Platt contended that rapid progress could be made in the biological sciences if well-formulated, alternative hypotheses were subjected to crucial experiments, designed to eliminate most of the alternatives. He characterized this approach as involving the following steps:

1. devising alternative hypotheses;
2. devising a crucial experiment (or several of them) with alternative possible outcomes, each of which will, as nearly as possible, exclude one or more of the hypotheses;
3. carrying out the experiment so as to get a clean result;
- 1.' repeating the procedure, making subhypotheses or sequential hypotheses to refine the possibilities that remain; and so on.

In the next section, some examples of how this 'strong inference' approach is coupled with the methods of experimental inquiry in several recent examples in microbiology are discussed.

Microbiology: Its Scope and Subject Areas; Representative Illustrations of the Philosophy of Method

The scope of microbiology is astonishingly broad. The most recent edition of Zinsser's well-known textbook comments on this subject, stated as follows:

With each passing year the term microbiology becomes a less satisfactory umbrella for the many disciplines that it attempts to cover. Bacteriology, immunology, virology, mycology, and parasitology have each long since become separate and independent disciplines.

Zinsser provides a continuing rationale for the subject area, however, noting that these numerous specialities "are treated together... simply because they deal with the agents that cause infectious diseases and with the mechanisms by which hosts defend against them". Be that as it may, any analysis of the philosophy of method of a domain that includes infection, bacteria, spontaneous generation and origin of life, the germ theory of disease, viruses, immunity, and chemotherapy must, of necessity, be selective. In the following paragraphs, several examples are discussed that are representative of methodology in microbiology. These illustrations will be used to provide a specific and accessible approach to the somewhat abstract topic of the philosophy of method in microbiology.

The Example of Koch's Postulates and AIDS Virology

As noted in the discussion earlier, self-conscious, explicit methodology is rare in the writings of microbiologists. One prominent and influential exception to this general rule are the Koch's postulates – more accurately termed the Henle–Koch postulates – developed to assess bacteriological causation of disease. About 10 years ago, these postulates returned to prominence at the center of a potentially momentous controversy in AIDS virology. The postulates can also be used as a framework for investigating another controversial example of disease causation – prions – as well as to point toward the limits of 'direct evidence' in microbiology. A brief account of the postulates' history and the philosophical presuppositions will facilitate an understanding of their role in the contemporary debate to be discussed later in this article.

The postulates have their proto-origin in Henle's work in 1840 and were then further developed by his pupil, the great microbiologist Robert Koch, in lectures in 1884 and 1890. There are several slightly different formulations of the postulates (see Evans, who follows Rivers as well as Zinsser), but the essence can be summarized as follows:

1. The infectious agent occurs in every case of the disease in question and under circumstances that can account for the pathological changes and the clinical course of the disease.
2. It must be possible to isolate the agent from all cases of the disease and to grow the agent in pure culture.
3. After being fully isolated from the diseased animals (or humans) and repeatedly grown in pure culture, it can induce the disease anew by inoculation into a suitable host.
4. In addition, some formulations add a fourth postulate:
5. The infectious agent occurs in no other disease as a fortuitous and nonpathogenic agent.

These are stringent conditions, and even at the time that Koch enunciated them, a number of etiological agents were known that did not fully meet the criteria, including bacteria isolated from typhoid fever and cholera. In the ensuing 100 years since the articulation of the postulates, several types of hitherto unrecognized forms of disease, including chronic diseases, cancer, and a number of viral diseases, have required the modification and extension of these postulates. In 1976, Evans attempted to bring together a number of these different themes into a 'unified' epidemiological conception of disease causation.

It is, however, the more traditional and stringent form of the postulates that was cited over the course of the past decade in an attempt by molecular virologist Peter Duesberg to question the causal relationship between HIV and AIDS. The theses of

Duesberg's work were that (1) HIV (the AIDS virus in either its HIV-1 or HIV-2 form) is neither necessary nor sufficient for AIDS, though HIV is a good 'marker' for American AIDS, and (2) AIDS is actually an autoimmune disease caused by as yet unknown pathogens, probably acting in concert with a variety of environmental insults, including hard psychoactive as well as medical drugs (AZT) and blood transfusion (particularly in the case of hemophiliacs). In the eyes of most scientists, Duesberg's principal arguments have been effectively answered, though Duesberg has continued to criticize the standard view in several recent books.

One of Duesberg's major arguments is that HIV fails to satisfy Koch's postulates. He wrote concerning the first of Koch's postulates that "there is no free virus in most – and very little in some – persons with AIDS, or in asymptomatic carriers". Though he admits that various viral elements (and, by definition of the disease, antibody to HIV) can be found in most or all of AIDS patients, he contended that HIV is not present in ways that can account for the loss of T cells or for the clinical course of the disease, which lags 8 or more years behind infection. Further, with respect to Koch's second postulate, Duesberg contends that there is an "often over 20% failure rate in isolation of HIV from AIDS patients". Finally, citing Koch's third postulate, Duesberg notes that HIV does not produce AIDS in any animal model (chimpanzees had been inoculated unsuccessfully), and the data from accidental inoculations of humans (through donor semen, laboratory accidents involving HIV researchers, and blood transfusions) are not consistent with the role of HIV as the sole cause of AIDS.

The response to Duesberg's arguments has been threefold. First, a number of commentators have pointed out that Koch's postulates listed earlier fail to be satisfied in a number of other diseases, primarily of the viral and immunological type encountered in AIDS, and that the postulates need to be taken as 'guidelines' and supplemented by broader epidemiological evidence. Second, when a broader, more epidemiological conception of causation is implemented using epidemiological data, that the evidence for HIV as the cause of AIDS is overwhelming. Finally, molecular investigations of HIV pathophysiology have deepened in recent years. New coreceptors for the virus have been identified that explain some resistance to HIV and may also help explain its oddly delayed pathogenesis. These receptors have also permitted better animal models of HIV/AIDS to be created. Duesberg has rejoined to this criticism, arguing that appeals to epidemiological considerations do not make the case that the proponents of HIV think they do and continues to aggressively defend his own theory.

It is not the purpose of this article to delve further into the details of the ongoing controversy regarding HIV and AIDS, but several points need to be highlighted that illustrate the role of the different philosophies of method involved. First, problems with the failure of HIV to satisfy Koch's first postulate have led to further speculations about the mechanism(s) of T-cell depletion. These speculations include syncytia formation, 'co-factor' pathogens, HIV as the trigger for an autoimmune disease, and, most recently, the proposal of a 'super-antigen' theory. Investigators generally believe that the evidence for these hypotheses are 'indirect', at best, and that more 'definitive or direct' proof is needed. Thus, the Henle-Koch postulates provide a framework and the failure to satisfy them in any simple way should provide the motivation for additional investigation, which may move the subject more in the direction of 'direct' evidence for explanatory models of AIDS pathogenesis. In the next illustration of the philosophy of method, another example of how ambiguous results that do not fully meet the requirements of Koch's postulates is examined, which raises the question of whether fully conclusive evidence is ever forthcoming in microbiology. The last example of just how 'direct' evidence can be obtained will partially answer this question affirmatively, with the continuing caveat, however, that in science, even direct proof continues to remain somewhat conditional.

Prions and the Question of the Causative Agents of the Transmissible Spongiform Encephalopathies

Modifications needed to extend Koch's postulates to take into account later microbiological developments are also a useful framework for a consideration of the cause of the transmissible spongiform encephalopathies (TSEs). These diseases include Creutzfeldt-Jakob disease (CJD) in humans, scrapie in sheep, and bovine spongiform encephalopathy (BSE), or 'mad cow' disease, in cattle. A number of investigators have attempted to determine the etiological agents and the details of the pathogenesis of the TSEs. At present, TSEs are generally thought to be caused by a novel infectious agent, a 'prion' – a term coined by S. Prusiner, to represent a 'proteinaceous infectious particle'. Prusiner received a Nobel Prize in 1997 for his accomplishments in this area and was cited for his 'discovery of 'Prions – a new biological principle of infection'.' That prions are the fundamental cause of TSEs is still somewhat controversial, and an alternative viral causation hypothesis continues to have its defenders.

If one followed Koch's postulates, as outlined previously, in the TSE area, one would attempt to (1) show the (various) infectious agent(s) occurs in every case of the diseases and accounts for the pathogenesis, (2) isolate the agent and purify it, and (3) use the purified agent(s) to induce the disease(s) in new hosts. In addition, one might want to (4) show the agent does not occur in any other disease as a nonpathological agent. Though Prusiner does not explicitly use Koch's postulates in his various writings on prions and TSEs, the postulates can function as a framework to approach his various arguments. Prusiner's early work was directed at the sheep TSE, scrapie. Following work by Alper that suggested the infectious agent was a protein that did not include nucleic acid, Prusiner was able to show that scrapie prions contained a protein he called PrP, short for 'prion protein'. These proteins are also unusually resistant to degradation by protease enzymes. Working with Leroy Hood, the protein was then partially sequenced, and the sequence used to construct a probe that could identify the genetic source of the protein. Remarkably, it turned out that the *PrP* gene can be found in hamsters, mice, and humans, but, most of the time, cells that make PrP are not pathological. An unorthodox, unprecedented, but possible, explanation was that PrP could exist in two different tertiary forms with the same amino acid sequence: one normal, called 'cellular PrP' (PrP^C), and the other associated with scrapie, termed 'scrapie

PrP' (PrP^{Sc}). This heretical idea was subsequently confirmed and considerable work has been done that examines various conformational changes in PrP and their pathological effects.

Prusiner and his group initially attempted (implicitly) to conform to Koch's second postulate by using the *PrP* gene to generate pure copies of PrP. They thought they could then implement Koch's third postulate and, as they wrote, "inject the protein molecules into animals, secure in the knowledge that no elusive virus was clinging to them. If the infections caused scrapie, we would have shown that protein molecules could, as we had proposed, transmit the disease". But as Prusiner adds, "by 1986, we knew the plan would not work". It was difficult to induce the gene to make the high levels of PrP needed, and, in addition, the PrP that was made was the benign 'cellular' type.

An alternative strategy was then devised that looked to inherited, rather than transmissible, forms of the SEs. Gestmann – Straussler–Scheinker disease is a very rare familial human SE that Prusiner and other investigators were able to link with a point mutation in the *PrP* gene. This served as the backdrop for the creation of genetically altered mice carrying a mutated *PrP* gene. One could first examine whether the mutated gene in the transgenic mice produced scrapie and then whether brain tissue from these mice could cause scrapie in 'healthy' mice, albeit only healthy transgenic mice expressing a low level of mutant PrP. These events do, in fact, occur and are claimed by Prusiner in 1995 to be "solid evidence that the protein encoded by the mutant gene had been solely responsible for the transfer of the disease". Step back and examine this claim more carefully and also consider a critic's view of this 'solid' or 'persuasive' evidence.

Prima facie, the experiment seems to satisfy Koch's first postulate, since all of the transgenic mice making high levels of PrP did develop mouse scrapie. Transplanted infected brain tissue, however, caused only many (not all) of the recipients to develop the disease. A proponent of the competing viral hypothesis, B. Chesebro, finds the transgenic mouse experiment 'inconclusive'. He notes that the transgenic mice differ from all known TSE models, because no abnormal protease-resistant PrP – a hallmark of scrapie PrP – is detectable in the diseased brain tissue. Also, disease occurs only when the mutant gene is overexpressed, not when it is found in its normal site as a single copy. Finally, transmission by infected brain tissue is only successful in transgenic mice – the low-level PrP producers – and not in nontransgenic animals. Chesebro suspects that 'other molecules' from the diseased brains could be causative of the disease, and, further, doubts the utility of the transgenic model, because none of the transmitted materials has been demonstrated to have typical properties of TSE agents, such as resistance to inactivation by heat. Other investigators also believe that additional TSE experimental findings point toward something more than prions as the cause of these diseases, perhaps a virus.

The prion hypothesis and the competing viral hypothesis are, thus, not unambiguously and definitively tested by this transgenic model. But this is only one of a number of lines of evidence supporting the prion hypothesis, and this article cannot delve into the multiple arguments and counterarguments in support of and against the prion view, which continue to evolve (see, e.g., the very recent report by J. Safar and colleagues in *Nature Medicine*, that provides data that different protein conformations are responsible for variations in prions' 'strains'). This fragment of the story, however, does suggest that Koch's postulates can be a useful framework within which to analyze possible etiological agents of disease, albeit one that needs extensions. Such extensions include both new understandings of molecular biological processes never dreamed of by Koch, as well as powerful new experimental techniques, such as the use of transgenic and knockout animals. But the story also indicates how difficult it is to obtain conclusive or 'direct' evidence of a causal hypothesis in microbiology, particularly in the still comparatively early stages of an investigation of a novel model of infection, even with this new powerful molecular knowledge and associated techniques.

The Example of the Isolation of the Repressor

The third example illustrating the application of methods of experimental inquiry is drawn from molecular genetics and involves progress in clarifying the nature of the mechanism of genetic control in bacteria, more specifically, the development and testing of the operon model of genetic regulation. The model, which is principally due to the work of Jacob and Monod, developed over a number of years. The initial form of the mechanism dates from 1960 to 1961 and has had a most important impact on both experiment and theory construction in molecular biology (and in embryology). It has been extraordinarily well corroborated by a variety of experiments. It was further developed in the 1960s, 1970s, and 1980s.

The model proposed the existence of a new class of genes, termed regulator genes, which were responsible for the synthesis of a substance, later determined to be a protein of about 160 000 molecular weight, which was termed a repressor. The repressor, in inducible systems, such as the *lac* region of *Escherichia coli*, binds specifically with a DNA region termed the operator locus. This operator has adjacent to it several structural genes, which are under the operator's control. When the repressor is bound to the operator, the associated structural genes are not transcribed into messenger RNA, and, accordingly, no proteins or enzymes associated with those structural genes are synthesized. An inducer can specifically interact with the repressor, altering its three-dimensional structure, and thus render it incapable of binding to the operator. The enzyme RNA polymerase, which attaches to a DNA sequence called a promoter in the presence of a protein called CAP and which can transcribe the structural genes, is then no longer prevented from initiating transcription of the structural genes adjacent to the operator, and mRNA synthesis and then protein synthesis commence. Repressible systems employ a similar regulatory logic, only, in that case, the initially ineffective repressor is aided in its operator-binding capacity by an exogenously added corepressor. It has been often noted by biologists that such a regulatory system is most useful to the organism since it allows unnecessary genes to be turned off when the proteinaceous enzyme products of those genes are not required for a metabolic process. This results in energy saving and is conceived of as evolutionarily useful to the organism.

In spite of the breadth of evidence for the operon model when it was first proposed in 1961, it can be said that the evidence, at that time, was primarily of an indirect genetic type. Monod in his Nobel lecture suggested, for example, that in the early 1960s the repressor – the crucial regulatory entity – seemed “as inaccessible as the matter of the stars”. The difficulty of being able to provide more direct biochemical evidence for the existence of the repressor and its postulated properties stimulated at least one alternative theory of genetic regulation, involving a mechanism different from that of the operon model.

In 1966, however, W. Gilbert and B. Müller-Hill reported that they had been able to isolate the elusive repressor, and, in 1967, the same authors were able to demonstrate that the repressor bound directly to the operator DNA. These experiments were most important for the field of regulatory genetics, and they were confirmed by Mark Ptashne’s essentially simultaneous isolation of the repressor in the phage λ system and the discovery that it also bound to DNA. These experiments, and the analyses of the experimental results, illustrate both the application of Mill’s methods and Platt’s ‘strong inference’.

Gilbert and Müller-Hill noted in their article reporting their results that though they felt the Jacob and Monod model to be the simplest, other models would also “fit the data” available. “Repressors”, they continued, “could have almost any target that would serve as a block to any of the initiation processes required to make a protein. A molecular understanding of the control process has waited on the isolation of one or more repressors”. Isolating the repressor was most difficult because of the hypothesized very low concentration of repressor in the *E. coli* cells. Gilbert and Müller-Hill solved this problem by looking for and finding a mutant form of the bacteria (i^1 or tightbinding), which produced a repressor with about a ten fold increased affinity for the inducer. As an inducer, the chemical IPTG (isopropylthiogalactoside) was used, which induces the *lac* operon but which, in contrast to lactose, is not metabolized by the induced enzyme. The repressor was detected by placing an extract of the i^1 mutant in a dialysis sac in a solution of radioactive IPTG (labeled to facilitate detection of very low amounts of it), and looking for an increased concentration of IPTG inside the sac after about 30 min (at 4°C).

Using the increased concentration as a sign of the presence of repressor, Gilbert and Müller-Hill purified the extract and analyzed the binding component. They discovered that the enzymes which would attack DNA and RNA would not destroy the inducer binding ability of the presumed repressor, but that an enzymes which attacked proteins would. Heating (above 50°C) also destroyed the ability to bind inducer. This was rather direct evidence (though still conditional on the hypotheses that (1) the enzymes possessed anti-DNA/anti-RNA capacity and (2) heat denatures proteins) that the repressor was a protein. The repressor (labeled with the radioactive inducer) was centrifuged and sedimented on a glycerol gradient. The ‘profile’ of the sedimented repressor indicated that it had a molecular weight of about 150 000–200 000.

Gilbert and Müller-Hill, in their article, cited what they termed ‘negative and positive controls’ on their supposition that they had isolated the repressor product of the *i* gene. The most important ‘negative controls’ involved examining the extracts from i^s (the superrepressed) and i^- (constitutive) mutants. The former type (i^s) presumably synthesizes a repressor that has lost the ability to bind inducer, and the latter (i^-) had been hypothesized to produce an (significantly) incomplete repressor. For both of these mutants, no binding of IPTG was observed. (Gilbert and Müller-Hill noted that “the various mutant forms of the *i* gene were put into identical genetic backgrounds, so that unknown variations from strain to strain could not confuse the issue”.)

Gilbert and Müller-Hill plotted graphs representing the binding constants of the wild type and i^1 mutant to demonstrate the essential identity of the repressors, which were used as positive controls. An examination of the binding ability of the repressor for various other substances, including galactose and glucose (and yielding a decreasing sequence of affinities), “gave further support for the [thesis that the isolated] material... [was] the repressor”.

In 1967, Gilbert and Müller-Hill used this partially purified radioactive repressor to test for *in vitro* binding to the operator of *lac* DNA. In this experiment, they used strains of bacteriophage that carried different forms of the *lac* operon in their DNA.

By sedimenting mixtures of the various strains of the phage DNA with the radioactive repressor, Gilbert and Müller-Hill found the following:

1. In the absence of inducer, the radioactive repressor binds to the DNA.
2. In the presence of IPTG, which releases the repressor from the DNA, no binding is observed.
3. The effect of the IPTG is specific, for substitution by a chemical ONPF (*o*-nitrophenyl-fucoside; a substance that binds to the DNA but does not induce) has no effect.
4. Use of two mutant phage o^c strains, in which the affinity of the operator for the repressor is expected to be weaker by a factor of 10 and 200, yielded sedimentation profiles in rough quantitative conformity with these binding expectations.

These experiments, which appear to utilize the methods of comparative experimentation or difference (the ‘negative control’) and concomitant variation (the ‘positive controls’), have been characterized as offering ‘direct’ evidence and ‘proving’ the hypotheses of the Jacob–Monod model. Clearly, they do so, however, with the aid of auxiliary hypotheses involving, among others (1) the effects of growth in radioactive media so as to specifically label the ‘observed’ entities and (2) the analysis of centrifugation and sedimentation techniques in density gradients. The experiments require a chain of reasoning. There is, in addition, (3), a very general negative auxiliary assumption that what is observed is not an artifact. It must be further emphasized that the direct proof of the Jacob–Monod operon model is contingent on the assumption that other, and perhaps more important and overriding, factors are not involved, that is, some competing, but as yet unarticulated, hypothesis that could account for all these results. The proposal of a novel mechanism of control that would account for the genetic data as well as Gilbert and Müller-Hill’s findings (perhaps by showing some of them to be artifacts), but which would disagree with basic tenets of the operon model cannot be logically excluded. The existence of Gilbert and Müller-Hill’s experiments are thus a ‘conditional’ direct proof, the conditions depending on (1) the truth of auxiliary hypotheses and (2) the nonexistence of an inconsistent competing theory or model that would account for the same data as the operon model.

Generalizing from this example, it is obvious that the ‘directness’ and force of the evidence is obtained by choosing one or more ‘central’ (roughly equivalent to ‘essential’) property(ies) of the hypotheses in the theory or model to be tested. In the operon model’s case, these properties were initially suggested in Monod’s work, namely, the repressor’s ‘recognition’ of the inducer and the operator.

In addition, plausible competitor theories and models are scanned to determine if the test condition(s), if realized, would support the model under test while falsifying the competitors. Recall that ‘genetic’ evidence was insufficient to do this, whereas the Gilbert–Müller-Hill experiments (as well as Ptashne’s) were. This exhibits Platt’s ‘strong inference’ in specific ways.

The evidence was considerably strengthened by providing both positive and negative controls. These controls are essentially equivalent to the well-known Mill’s methods of difference and concomitant variation, as discussed previously.

These three particular examples, the use of the Henle–Koch postulates to assess the causal role of HIV and the TSEs, and the employment of a strategy of strong inference implementing methods of difference and concomitant variation to identify and characterize the repressor, illustrate the application of several methodological themes found in microbiology. Each of these examples also indicates that the application of such methods requires creative insight coupled with detailed knowledge of the subject domain, as well as exemplary technique, in the case of laboratory investigations. In addition, the examples illustrate that the path from speculation and indirect evidence for scientific hypotheses to direct proof is difficult and frequently depends on background assumptions that themselves could, at some time, be called into question. Such a process of continued questioning of received assumptions, coupled with the proposal of new, precisely formulated hypotheses subject to experimental test and evaluation by rigorously applied scientific method, is the essence of excellent science, and though this process is typically implicit in microbiology, it is no less an important constituent of scientific progress in the subject.

Glossary

Bacteriophage Virus specific for particular strain of bacteria.

Epigenetic A phenotypic but not genotypic change.

Methyltransferase Enzyme methylating particular residues in a macromolecule.

Modification Chemical change of DNA/RNA bases or amino acids.

Promoter Sequence at which RNA polymerase initiates transcription.

Restriction Inactivation of DNA by nucleolytic cleavage.

S-adenosyl-L-methionine Universal methyl donor used by methyltransferases.

Abbreviations

cAMP cyclic AMP

Cap Cyclic AMP binding protein

CcrM Cell cycle-regulated methyltransferase

Dam Adenine methyltransferase

Lrp Leucine-responsive regulatory protein

OxyR Oxidative damage response

Pap Pyelonephritis-associated pili

PTM Post-translational modification

SAH S-adenosylhomocysteine

SAM S-adenosyl-L-methionine

Defining Statement

Methylation and many other covalent modifications occur in DNA, RNA, and protein. In DNA, methylated bases regulate chromosome replication, the cell cycle, DNA repair, and transcription of specific genes. RNA modification may be required for optimal ribosome function and translation. Protein modifications include methylation, acetylation and phosphorylation that regulate signal transduction during chemotaxis and response to other environmental cues, and play important roles in bacterial metabolism, pathogenesis and other cellular processes.

Introduction

Modification of polymers such as DNA, RNA, and protein generally occurs at the post-synthetic level. For example, methylation of bases in nucleic acids occurs after formation of the polymer rather than by incorporation of methylated precursors during synthesis. Methylation results from the action of enzymes, methyltransferases, which are very specific not only for the particular polymer but also for specific residues in defined sequences in the polymer. In some cases, the biological role for methylated residues of polymers has been elucidated. Although various modifications to particular polymers are possible, such as phosphorylation, thiolation, and acetylation, this review concentrates on methylation of macromolecules since this modification appears to be the most frequent and, currently, best understood. *Escherichia coli* will be used as a model because more information on the biochemistry and genetics of modification is available in this organism than any other.

[☆]*Change History:* January 2015, J-R Zhang, M Marinus, and H Deng added an Abstract and Figure 7, updated the sections of DNA methylation and other modifications (of proteins), and revised the reference section.

This article is an update of M.G. Marinus, Methylation and Other Modifications of Nucleic Acids and Proteins, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 287–295.

DNA, RNA, and Protein Methyltransferases

Methyltransferases catalyze the transfer of methyl groups from *S*-adenosyl-*L*-methionine (SAM) to specific residues in the polymer. For example, DNA adenine methyltransferase (Dam) from *E. coli* catalyzes the formation of *N*⁶-methyladenine at adenines in the sequence 5'-GATC-3'. Only the *N*⁶ position is modified and adenine residues in other sequences are not methylated nor are adenines in RNA. In double-stranded nucleic acids, methylation substrates are symmetric (5'-GATC-3'/3'-CTAG-5') and two independent methyltransferase binding events are required.

All methyltransferases acting on polymers use SAM as the methyl donor, which results in the formation of *S*-adenosylhomocysteine (SAH) after catalysis. SAH is a powerful inhibitor of methyltransferase action and has a physiological role in limiting the action of this class of enzymes. Amino acid sequence comparisons of the DNA methyltransferases suggests that they evolved from a common ancestral protein by gene duplication followed by extensive divergence. DNA cytosine methyltransferases, however, retain conserved amino acid sequence motifs suggesting a similar basic mechanism of catalysis. This mechanism involves the transient and covalent binding of the enzyme through nucleophilic attack of cysteine-177 to the number 4 carbon atom of the pyrimidine ring. This leads to the activation of the number 5 carbon to receive the methyl group from SAM. After completion of methyl group transfer, SAH is released and the enzyme dissociates from the substrate sequence. A similar mechanism of catalysis has been proposed for RNA methyltransferases.

The atomic structures of several DNA methyltransferases have been solved recently and in some instances, the structure of the enzyme bound to DNA. These structures have shown that the enzyme rotates the target nucleotide about 180° into a concave catalytic pocket. This rotation is accomplished without any breakage of chemical bonds and has been termed 'base-flipping' (Figure 1). Although the number of demonstrated examples of base flipping is currently limited, this mechanism is surprisingly elegant and simple. It is tempting to speculate that this may be the basic mechanism of action for DNA methyltransferases in general.

DNA Methylation

Methylation has been found in three nucleotides of bacterial DNA: *N*⁶-methyl-adenine (m6A), *C*⁵-methylcytosine (m5C), and *N*⁴-methyl-cytosine (m4C) (Figure 2). m6A and m5C widely exist in the genomes of fungi, bacteria and some Archaea, whereas m4C is exclusively found in bacteria. While the bases of some bacterial genomes are highly methylated, certain bacterial species have not detectable methylation. In *E. coli* strains, m6A and m5C represent 1–2% of the total bases. Bacterial viruses (phages) also can contain modified bases in their DNA and in the T-even group, which infects *E. coli*, 5-hydroxymethylcytosine is present instead of cytosine. Furthermore, one or more glucose residues are attached to this modified base. It is possible that the viral DNA is modified in this way so that it is protected from viral enzymes that degrade host DNA during infection.

In *E. coli* K-12, strains lacking all endogenous DNA methyltransferases have been constructed by genetic means and these have no detectable methylated bases in DNA. Such strains are viable as long as their ability to recombine DNA is not impaired. Recombination is required to repair the double-strand breaks that occur in the absence of *dam* methylation as a consequence of DNA mismatch repair. In other bacteria such as *Vibrio cholerae*, however, Dam methylation is an essential function probably for the initiation of chromosome replication. Since endogenous DNA methylation in *E. coli* blocks the action of some restriction

Figure 1 Methylation by base flipping. An adenine residue is flipped out of the DNA helix into the active site of Dam methyltransferase where a methyl group from SAM is added to the *N*⁶ position of the base.

Figure 2 Common methylated bases in DNA. The structures of 5-methylcytosine, 4-methylcytosine, and 6-methyladenine are shown.

endonucleases used for recombinant DNA technology, plasmid DNA is often prepared from these methylation-deficient strains to avoid this problem.

DNA methylation is traditionally detected by biochemical methods such as thin restriction digestion, layer chromatography, high-performance liquid chromatography, mass spectrometry, and nanopore amperometry. Recent advancement in DNA sequencing technology has made it possible to characterize the methylation status of the entire genome, so called methylome. Treating genomic DNA with sodium bisulfite followed by parallel DNA sequencing (termed bisulfite sequencing) has allowed genome-wide detection of cytosine methylation sites. Single molecule, real-time (SMRT) sequencing can identify methylated adenines and other bases in a high throughput manner. While bisulfite sequencing is predominantly used in eukaryotic organisms, the SMRT sequencing method has been applied to detect the DNA methylations of the entire genome or methylomes of pathogenic *E. coli*, *Helicobacter pylori* and several other bacteria. These technologies have revolutionized the research on DNA methylation.

Restriction and Modification of DNA

DNA transfer of plasmid, bacterial virus or chromosomal DNA is thought to occur at a low level between bacterial strains and species. Most bacteria have surveillance systems that allow them to differentiate 'foreign' DNA from their own DNA. The basis of one of these systems is the possession of an endonuclease (e.g., *EcoRI*) that recognizes a specific sequence in DNA (5'-GAATTC-3') and cleaves it only when unmethylated. A corresponding DNA methyltransferase (*M.EcoRI*) recognizes the identical sequence and modifies it to 5'-GA^mATTC-3', where the second A is methylated. Therefore, bacteria possessing the *EcoRI* methyltransferase will have all susceptible sequences methylated and thus be immune to *EcoRI* endonuclease action. Introduction into the bacterium of homologous or heterologous DNA lacking the specific *EcoRI* modification leads to recognition and cleavage of such DNA and subsequent degradation by the endonuclease.

A very large number of restriction enzymes have been isolated from bacteria, each having a unique DNA recognition sequence. The availability of this battery of enzymes has been a major contributing factor to the success of recombinant DNA technology in allowing the mapping of genes and their isolation from chromosomes.

One other interesting aspect of restriction/modification is that it can be the basis of epigenetic behavior. For example, bacterial viruses containing DNA not modified at *EcoRI* sites will not kill bacteria, since their DNA is degraded upon entering the bacteria. However, at a low frequency, a few virus DNA molecules survive because they have been methylated and, when these are tested again, they now infect and kill the same bacteria at high efficiency. The virus has not mutated in any way; the only difference is that its DNA has become methylated and thus is now resistant to *EcoRI* endonuclease action. Since methylation is dependent on the host in which the virus was last propagated, it is not a heritable change but an epigenetic one.

A second system that bacteria possess to protect themselves from foreign DNA is the ability to detect 'foreign' modifications on such DNA and degrade it using specific endonucleases. For example, in the early days of recombinant DNA technology, it was difficult to isolate genes from animals and plants in the standard bacterial host, *E. coli* K-12. We now know that this failure was due to the destruction of the DNA because it contained methylated cytosine and was recognized by an endonuclease called Mcr (for methylcytosine restriction). This enzyme recognizes and cleaves any methylcytosine-containing DNA that does not have the *E. coli* K-12 signature cytosine methylation. Currently, *E. coli* strains lacking all known restriction systems are used to successfully isolate human and plant genes.

Dam Methylation

In some bacteria (and all eukaryotes) most methylated bases are not part of restriction/modification systems. The Dam and Dcm methylation systems of *E. coli* K-12 are the best characterized of these. The *dam* and *dcm* genes encode DNA adenine (Dam) and DNA cytosine methyltransferases (Dcm), respectively. Dam modifies the adenine residue in 5'-GATC-3' sequences to N⁶-methyladenine and Dcm modifies the second cytosine in 5'-CCAGG-3' and 5'-CCTGG-3' sequences to 5-methylcytosine. The combined action of these two methyltransferases is responsible for about 99% of the total methylated bases in DNA. The methyltransferase (*M.EcoK*) that is part of the modification/restriction system contributes the remaining small percentage of the total owing to the infrequent occurrence of the DNA sequence it recognizes.

Figure 3 Promoters and terminators contributing to *dam* gene transcription. Five promoters (P) and one transcriptional terminator (T) contribute to transcription of the *dam* gene. The major contributing promoter is P2 which is growth-rate regulated. Reproduced from Marinus MG (1996) Methylation of DNA. In: Neidhardt FC, Curtiss R, Ingraham JL, et al. (eds.) *Escherichia coli and Salmonella: Cellular and Molecular Biology*, 2nd ed., pp. 861–886. Washington, DC, with permission of the American Society for Microbiology Press.

The *dam* gene is regulated at the level of transcription by at least five promoters and one terminator sequence (Figure 3). The major promoter, P2, is located about 3000 bases upstream of the gene and it produces a multigene transcript for the *aroK*, *aroB*, *damX*, *dam*, and *trpS* genes. This promoter is growth-rate regulated; the faster the growth rate the greater the frequency of transcript initiation. This is very logical because at slow growth rates, the Dam level should be lower than in fast growing cells to prevent premature methylation of hemimethylated DNA that might lead to increased spontaneous mutation and alteration of nucleoid structure (see below). The rationale for growth rate regulation for the *aro* (aromatic amino acids), *damX* (function unknown), and *trpS* (tryptophanyl-tRNA synthetase) genes is not known.

The mode of transcriptional regulation of the *dcm* gene is not known. The gene order is of interest because the last 20 bases of *dcm* overlap the beginning of the *vsr* gene, the product of which is an endonuclease necessary for very short patch (VSP repair; see 'Dcm methylation'). Dcm and Vsr proteins are translated from the same mRNA transcript in different reading frames but the mechanism by which this occurs has not been elucidated since ribosomal frameshifting has been excluded. Coupling translation of Vsr to Dcm may ensure that VSP repair is available when Dcm methylation is active.

Dam-Directed Mismatch Repair

The concentration of Dam in the cell is regulated to be less than that needed for rapid methylation of all available sites in the DNA. This results in under-methylation of the newly synthesized DNA chain relative to the parental strand, which is fully methylated. This difference in methylation state is exploited by a DNA repair system (Dam- or methyl-directed DNA mismatch repair) that removes errors generated by the replication machinery from the newly synthesized strand (Figure 4). If the replication machinery makes a mistake, it will be present in the newly synthesized (unmethylated) strand as a base mismatch and be recognized by the MutS protein. After specific recognition, MutL is recruited followed by MutH that activates its latent endonuclease activity to nick the unmethylated strand (Figure 4). The UvrD helicase enters at the nick and unwinds the DNA making the nicked strand available for exonuclease digestion. The gap so formed is filled by DNA polymerase III, the replicative enzyme, followed by ligation by DNA ligase and methylation of the GATC sites by Dam methyltransferase. Note that MutH can cut only if the substrate DNA is hemimethylated; fully methylated is not a substrate for MutH endonuclease action, thereby targeting repair to the region just behind the replication fork. Inactivation of this mismatch repair pathway increases the spontaneous mutation frequency 100- to 1000-fold relative to the wild-type strain indicating its importance in proofreading newly replicated DNA. In *dam* bacteria, discrimination between the new and old strands is lost and, therefore, half the time it is expected that mismatch repair introduces mutations into the DNA resulting from replication errors. This is reflected in the mutator phenotype associated with the *dam* mutant.

Initiation of Chromosome Replication

Chromosome replication in *E. coli* begins at a sequence called *oriC* (origin of replication), which has about tenfold more GATCs than expected on a random basis. Once chromosome duplication begins, it is important to suppress further initiation until the cell requires it. It appears that *dam* methylation is involved in the suppression mechanism. Upon replication, the *oriC* region becomes hemimethylated and is bound by SeqA protein and 'sequestered' as is the nearby *dnaA* gene. At a later stage in the cell cycle, SeqA dissociates and the free *oriC* region is methylated by Dam thereby preparing it for the next initiation event. Experimental evidence supporting this model includes the inability of hemimethylated DNA molecules to replicate in *E. coli dam* mutants. The SeqA protein binds with high affinity to hemimethylated DNA containing two or more GATC sites on the same face of the DNA and so only a subset of all GATCs are bound.

Dam methylation also affects the frequency of initiation at *oriC* by multiple mechanisms. First, initiation of unmethylated *oriC* DNA appears to be less efficient than with fully methylated DNA. Second, DnaA is the key protein acting at *oriC* to initiate the process and transcription of the *dnaA* gene is regulated, in part, by Dam methylation of its promoter region, and thus there may be a reduction in the effective concentration of this protein in a *dam* mutant. Third, in wild-type *E. coli* containing multiple copies of *oriC*, initiation occurs simultaneously at all origins. In *dam* mutants, however, initiation at multiple *oriCs* occurs at random throughout the cell cycle indicating that Dam methylation controls synchronization. All of these mechanisms may contribute to the reduced efficiency of chromosome initiation at *oriC* in *dam* mutants.

Figure 4 Dam-directed mismatch repair in *E. coli*. The top of the figure shows DNA immediately behind the replication fork in which the 'old' top strand is methylated and the 'new' strand is not; it also contains a base mismatch (carat) created as a replication error. The mismatch is recognized and bound by MutS followed by recruitment of MutL and MutH to form a ternary complex. The formation of this complex is thought to involve DNA looping to bring the mismatch and a GATC sequence in close proximity but the details are unclear. In the ternary complex, the latent nuclease activity of MutH is activated, which cleaves the new unmethylated strand 5' to the GATC sequence. The nick created by MutH serves as an entry site for the UvrD helicase, which unwinds the DNA exposing single-stranded DNA which is digested by one or more of the following exonucleases: *RecJ*, *ExoVII*, *ExoX*, or *ExoI*. The exonuclease(s) used depends on the relative orientation of the mismatch to the GATC sequence; in the figure, the direction of UvrD unwinding is 5' to 3' and so either *ExoVII* or *RecJ* or both are needed. If the mismatch was to the 'right' of the GATC sequence, UvrD would unwind in the 3' to 5' direction and *ExoX* and/or *ExoI* would digest the single-stranded DNA. The gap created by nuclease digestion is filled in by DNA polymerase III. The resulting nick is closed by DNA ligase and eventual Dam methylation in the newly synthesized strand precludes any further repair. Reproduced from Marinus MG (2005) Dr. Jekyll and Mr. Hyde: How the MutSLH repair system kills the cell. In: Higgins NP (ed.) *The Bacterial Chromosome*, pp. 413–440. Washington, DC, with permission of the American Society for Microbiology Press.

Nucleoid Structure

Hemimethylated DNA occurs immediately behind the replication fork and three proteins are known to bind to such DNA: Dam, MutH, and SeqA. Overproduction of Dam leads to premature methylation of hemimethylated DNA and a high level blocks MutH action thereby preventing mismatch repair and increasing the frequency of spontaneous mutation. There is a substantial effect on SeqA binding even in low-level Dam-overproducing cells where Dam out competes SeqA for GATC binding. This is equivalent to SeqA not acting at all and leads to an alteration in supercoiling of the chromosome leading to a perturbed global transcription pattern. To maintain proper nucleoid structure, therefore, it is crucial that cells regulate the Dam/SeqA protein ratio.

Transcriptional Regulation of Gene Expression

Dam methylation can influence gene expression by two different mechanisms: direct and indirect. The direct mechanism involves RNA polymerase binding to promoter regions that have 5'-GATC-3' in one of two critical regions; the '-10' and the '-35' hexamers. Methylation at these hexamers can increase, decrease, or have no effect on transcription initiation, depending on the specific promoter. Methylation of the *trpR* (tryptophan repressor) and *sulA* (suppressor of filamentation) gene promoter hexamers reduces transcription initiation while methylation of one of the two *dnaA* gene promoters increases it. The promoter regulating transposition of the tetracycline-resistance element Tn10 is active only in a hemimethylated state, which occurs during the brief period when it is replicated. Transposition is thereby coordinated with the cell cycle.

The second mechanism by which Dam methylation can control gene expression relies on competition for overlapping DNA binding sites between Dam and regulatory proteins such as transcriptional activators and repressors. Methylation of the sequence bound by the regulatory protein then locks gene expression into a particular mode. For example, Cap (cyclic AMP – cAMP binding protein), with cAMP, binds to specific sequences upstream of many promoters and acts to increase the basal level of transcription. The consensus 22 bp recognition site for Cap-cAMP is 5'-AATGTGATATCACATTT-3' and a high-affinity site contains the TGTGATC sequence, which overlaps with the Dam recognition sequence. Methylation of this sequence can cause interference with Cap-cAMP binding, thus preventing high-level expression of the gene. In addition to Cap-cAMP, the transcriptional activators Lrp (leucine-responsive regulatory protein) and OxyR (oxidative damage response) have recognition sites that can overlap with GATC-sequences

and show differential DNA binding depending on the methylation state of this tetra-nucleotide. For example, the *agn43* (antigen 43) gene of *E. coli* encodes an auto-transporter protein that causes cells to aggregate and form precipitates in culture media. The gene has three – GATC- sites in its promoter region and their methylation leads to full transcription initiation (Figure 5). During replication of the gene, Dam or SeqA or OxyR can bind the hemimethylated DNA. Dam binding to the GATCs allows continued transcription while SeqA binding is transient and favors its eventual replacement by Dam. OxyR binding, however, is tighter than SeqA and can exclude Dam so that after a second round of replication a fully unmethylated promoter region with bound OxyR is created and gene transcription cannot occur. Other examples of such regulatory circuits involving GATC sequences and differential DNA binding include the *pap* (pyelonephritis-associated pili) operon of uropathogenic *E. coli*, the K88 pili associated with diarrheal *E. coli* infections and the Pef fimbriae of *Salmonella enterica*. These regulatory circuits can also include other DNA-binding proteins such as H-NS and the sigma factor RpoS. Note that, expression of genes controlled in this way constitutes epigenetic behavior.

High-level gene expression is achieved only if transcriptional activators, such as Lrp and Cap-cAMP, are continuously bound to the site preventing access to Dam and subsequent modification. In practice, such unmethylated sites are identified in chromosomes by their lack of Dam methylation and about 50 such sequences have been detected. The methylation state of such sites can change depending on the need for the gene products involved.

Posttranscriptional Regulation of Gene Expression

There are three examples of posttranscriptional gene regulation influenced by Dam. First, the VSP repair system corrects T/G mismatches arising from deamination of 5-methylcytosine (Figure 6). VSP repair is reduced in *dam* cells by an unknown indirect mechanism since there are no GATC sites in the presumed regulatory regions of the VSP repair genes. Second, a similar situation occurs in the *std* operon of *S. enterica*, which regulates production of fimbriae that are important for long-term carriage in mice. Third, the Tir effector of enterohemorrhagic *E. coli* is essential for virulence and is secreted from bacterium into human cells to form tight binding between them. In a *dam* mutant of this bacterium, the abundance of the Tir protein is dramatically increased but the mRNA level is not. In none of these three cases has the mechanism of posttranscriptional regulation been elucidated.

Control of Bacteriophage DNA Packaging into Virions

Bacteriophage P1 encodes its own *dam* gene and Dam methylation is essential for successful production of new bacteriophage after infection of the host. Introduction of bacteriophage DNA into the head (capsid) of the maturing virus particle is the critical step at which Dam methylation acts. The DNA is synthesized in long pieces (concatamers) that need to be cut into smaller pieces at *pac* sites (containing seven GATC sequences) in order to fit properly into the head. This process requires that the DNA be fully methylated at

Figure 5 Regulation of *agn43* gene transcription in *E. coli*. The promoter region of the *agn43* gene contains three GATC sequences that must be methylated (Me) for the gene to be expressed. Replication of the gene will cause transient hemimethylation allowing one of three proteins can bind this DNA. Dam action will methylate the GATCs on the new strand thereby preserving expression of the gene. SeqA can also bind but is easily displaced by Dam resulting in methylation and continued gene expression. OxyR binding prevents Dam action and after a second round of replication the GATCs are unmethylated and transcription is prevented. Reproduced from the *Journal of Bacteriology* 184, 3338 (2002), with permission of Dr. Marjan van der Woude and the American Society for Microbiology Press.

Figure 6 VSP repair of deaminated 5-methylcytosine. 5-Methylcytosine deaminates spontaneously to thymine thereby creating a T-G mismatch. This is acted upon by the VSP repair system, which removes the base by the action of the Vsr glycosylase and cleavage of the DNA backbone. DNA polymerase I is used to fill-in the missing base and DNA ligase seals the remaining nick. Dcm methyltransferase transfers a methyl group to the cytosine to restore the original methylated base. The T-G mismatch is infrequently also a substrate for Dam-directed mismatch repair which can convert the GC to an AT base pair creating a mutation.

pac sites since it is only in this state that the DNA can be cleaved by the viral p9 enzyme. On any one concatamer, however, all but one *pac* sites are hemimethylated due to binding, but not cleavage, of P9. Obviously, lack of methylation prevents successful encapsidation of DNA and the production of complete virus particles.

There are many bacteriophage that encode a *dam* or *dam*-like gene. At this time, other than bacteriophage P1, there is no known role for the function for these *dam* gene products.

Dam as a Virulence Factor in Pathogenic Bacteria

Loss of Dam methylation in certain strains of pathogenic bacteria, such as *Salmonella*, *Haemophilus*, and *Yersinia*, reduces virulence considerably in animal models, probably due to changes in gene expression in pathogenicity islands in the absence of methylation. In other pathogens such as *Shigella flexneri* and enterohemorrhagic *E. coli*, loss of Dam has no effect on virulence. In *Pasteurella multocida* and *Yersinia pseudotuberculosis*, virulence is altered when Dam is overproduced probably by preventing binding of SeqA to hemimethylated DNA and consequent alteration of chromosome structure leading to a change in global gene expression.

Plasmids bearing virulence determinants can be transferred from cell to cell by conjugation. The pSLT virulence plasmid of *Salmonella* can transfer at high frequency from a *dam* mutant because the transfer (*tra*) operon is de-repressed. Transcription of the *traJ* gene, which encodes a transcriptional activator of the *tra* operon, is normally reduced in wild-type due to GATC sites in the promoter region. In addition, transcription of *finP*, a small regulatory RNA that antagonizes *traJ* expression, is also decreased in *dam* cells.

Dcm Methylation

The DNA cytosine methyltransferase (Dcm) in *E. coli* is an orphan cytosine-5 DNA methyltransferase, which methylates the second cytosine in the sequence 5'CCWGG3'. Dcm-mediated methylation is highly conserved in *E. coli* isolates. Unlike Dam methylation, a physiological role of 5-methylcytosine is not completely clear. Given its widespread occurrence in bacteria, however, there must be some evolutionary advantage in retaining it. 5-Methylcytosine in DNA is spontaneously converted into thymine at a low level. This conversion produces a thymine-guanine base mispair and *E. coli* and other bacteria have evolved a repair system (VSP repair) that converts the thymine back into cytosine and then Dcm methylation to 5-methylcytosine (Figure 6). The Vsr glycosylase, which removes the thymine, is encoded by the *vsr* gene. *vsr* overlaps the *dcm* gene by seven codons and both are translationally coupled. The thymine-guanine mispair is also a substrate for Dam-dependent mismatch repair, which can convert it into a thymine-adenine base pair thereby producing a mutation. Mutation at 5-methylcytosine residues is the most common C to T base pair alteration in *E. coli* and probably occurs most frequently by replication of the T-G mismatch before VSP repair. Dcm can influence drug resistance and the expression of ribosomal protein genes during stationary phase influence stationary phase gene in *E. coli*.

YhdJ Methylation

Annotation of the *yhdJ* gene of *E. coli* K-12 suggested that the gene product might encode a methyltransferase based on similarity of certain amino acid motifs that occur in this class of enzymes. Recently, the *yhdJ* gene was cloned and its product is indeed a DNA methyltransferase that methylates the 3' adenine in the sequence 5'-ATGCAT-3'. The *yhdJ* gene, however, is not essential for growth of *E. coli* and is not expressed under normal laboratory growth conditions and consequently its biological role is unknown.

CcrM Methylation

Although the CcrM (cell cycle-regulated methyltransferase) and its homologues have been found in *Agrobacterium*, *Sinorhizobium*, and *Brucella*, the enzyme was discovered in *Caulobacter crescentus*; and it is in this organism where its properties have been most fully characterized. In all these organisms, CcrM is essential, and in *Caulobacter* it contributes to control the cell cycle. The *Caulobacter* life

cycle can be divided into nonmotile stalked and motile swarmer forms where chromosome replication occurs only in the former to produce a stalked and a swarmer daughter cell. Both nascent daughter cells, therefore, contain hemimethylated DNA and in the late stage of chromosome duplication, but before cell division, the *ccrM* gene is expressed and the methyltransferase methylates the adenine in 5'-GATC-3' sequences of the entire chromosome. Once the origin of replication (*Cori*) is fully methylated it is bound by the CtrA protein to prevent initiation of chromosome replication. In the swarmer cell, CtrA remains bound while in the stalked cell, CtrA is destroyed by proteolysis allowing initiation to proceed on a fully methylated *Cori*. After cell division, the CcrM protein is degraded preventing further methylation thereby ensuring the origin is hemimethylated and inert for further initiation.

Transcription of the *ccrM* gene occurs only in the hemimethylated state and is activated by CtrA, which binds to two 5'-GATC-3' sequences in the upstream regulatory region of *ccrM*. This arrangement ensures that the concentration of CcrM increases toward the end of the replication cycle. The synthesis of CtrA is also regulated by CcrM methylation. Two 5'-GATC-3' sequences also occur in the upstream regulatory region and one is close to the -35 hexamer of the promoter. This promoter also is active only when hemimethylated, and the expression of the gene is, therefore, co-coordinated with the cell cycle. The *ctrA* gene is located proximal to the origin relative to the *ccrM* gene thereby ensuring the proper sequence of gene expression and regulation. This arrangement is very reminiscent of the DnaA-*oriC* interaction described above for *E. coli*.

RNA Modification

More than 100 modifications have been found on four canonical nucleotides of RNA. Recent progress in high throughput detection of RNA modifications in eukaryotic organisms makes it possible to map some of RNA modifications at the genome scale, such as N⁶-methyladenosine (m⁶A) and 5-methylcytidine (m⁵C). While there are extensive modifications in mRNAs and non-coding RNAs of eukaryotic organisms, our understanding on RNA modification in bacteria is currently confined to ribosomal and transfer RNA. The following sections will focus on RNA modifications in bacteria.

RNA Methylation

In contrast to DNA, ribosomal and transfer RNA are extensively modified and it has been estimated that there must be at least 80 RNA modification enzymes in *E. coli* and of these at least 20 are RNA methyltransferases. Only a few of these enzymes have been characterized to date. There are no reports of methylated bases in messenger RNA but this may be difficult to measure given the inherent instability of this class of molecules.

Two tRNA methyltransferases, TrmD and TrmU, are essential for cell viability and TrmD methylates guanine at position 37 and TrmU is responsible for 5-methylaminomethyl-2-thiouridine formation. The reason for the absolute requirement of these modifications for cell viability is not known but most likely reflects their contribution to the fidelity of translation through tRNA-mRNA codon interaction. This idea is supported by the observation that nonlethal point mutations in these genes lead to excessive ribosomal frameshifting during translation.

Although deletion of the genes for other known RNA methyltransferases does not lead to lethality, many of these strains show subtle effects on translation. For example, ribosomal subunits lacking dimethyladenine from the *ksgA* (kasugamycin-resistant) mutant strain have decreased affinity for each other and an increased requirement for a translation initiation factor.

Other RNA Modifications

Deletion of the genes for most known RNA modification enzymes does not result in loss of viability although multiple deletion of these genes encoding enzymes with overlapping specificities has not been tested. The single gene deletion mutants may show subtle effects on the rate of translation or the ability of tRNAs to bind to cognate codons. Mutant strains lacking ribosomal modifications are often resistant to antibiotics (kasugamycin, viomycin), again suggesting subtle alterations in the translation apparatus.

Protein Modification

Methylation

Methylation can occur at side chain nitrogens in arginine, lysine, *iso*-aspartic acid, histidine, glutamine, and glutamic acid residues in proteins. Only a few protein methyltransferases, however, have been purified and characterized.

Bacteria exhibit chemotactic behavior toward certain chemicals to which they are either attracted or repelled. Receptors in the cell membrane are used to monitor the concentration of such chemicals and to signal the flagella motor to turn on or off, which, in a cumulative manner over time, results in movement of the cell either toward or away from the chemical. Methylation/demethylation at four glutamic acid residues on the CheR membrane receptor protein is part of the signaling cascade. A methyltransferase and a methylesterase (which removes the methyl groups) have been implicated in this process. Inactivation of either one of these enzymes leads to loss of chemotactic behavior. Presumably, changes in the cell's environment alter the pattern of methylation/demethylation at the four glutamic acid residues and the subsequent response of the flagellar motor. CheR methylation/demethylation is the only known instance of a reversible methylation involved in regulating a protein's activity.

The *prmA* (protein methyltransferase) and *prmB* genes encode protein methyltransferases that form methyllysine on protein L11 and N⁵-methylglutamine on protein L3, respectively. Although these methyltransferases are found in many bacterial species, *E. coli* strains deleted for each of these genes are viable indicating that these methylated derivatives are not essential for protein synthesis. The *prmC* gene of *E. coli* encodes a protein N-5 glutamine methyltransferase that methylates residues in release factors 1 and 2. Methylation of these release factors greatly increases the efficiency of the termination reaction of translation when proteins are released from the ribosome. Further evidence for the importance of this methyltransferase is that *E. coli* strains deleted for the gene are not viable.

Flagella are responsible for the bacterium's movement, and are composed of a structural protein called flagellin. The FlhB protein methyltransferase produces N-methyllysine in flagellin. The physiological role for this methyltransferase, however, is unclear since *E. coli* bacteria missing this enzyme are not impaired in flagellar locomotion. Similarly, mutant strains of *E. coli* lacking methylated lysines and glutamic acids in ribosomal proteins show no impairment of growth. Spontaneous chemical degradation of aspartic acid to iso-aspartic can occur and subsequent methylation of the iso-aspartic residue is part of a protein repair pathway. Mutations eliminating the methyltransferase, however, appear to have no effect on *E. coli* viability.

Pili (fimbriae) are rod-like appendages the bacterial cell uses to attach to various cells. For example, pathogenic bacteria often use pili to attach to host cells in order to infect them. Pili are composed of pilin protein, and type 4 pilin has been reported to contain N-methylphenylalanine at its N-terminal end. Methylation may be necessary as a transport signal for pilin to reach its destination. However, there are no reports in the literature on how this methylated amino acid is formed, although the action of a specific methyltransferase would seem probable.

The translation elongation factor, EF-Tu, is monomethylated at lysine-56 in growing bacteria but is gradually converted into dimethyllysine as *E. coli* cells enter the stationary phase of growth. The physiological significance of this observation currently remains unknown.

Recent studies have shown that methylation plays a role in virulence of *Rickettsia*. Two protein lysine methyltransferases were identified that preferentially methylate outer membrane protein B (OmpB) to generate mono-, di-, and tri-methylated lysine residues. Using an *in vitro* methylation assay, the consensus motifs for methylation were characterized to be KX(G/A/V/I)N and KT(I/L/F). A correlation between the protein methylation states and virulence was found, indicating that lysine trimethylation is crucial for *Rickettsia* virulence.

Other Modifications

Over the last decade, proteomics technology has been rapidly developed for characterization of bacterial proteins. Many new protein post-translational modifications (PTMs) were identified including tyrosine phosphorylation. The most frequently observed PTMs include acetylation, carboxylation, citrullination, deamidation, glutathionylation, hydroxylation, methylation, methylthiolation, S-nitrosylation and nitration, phosphorylation, and proteolysis. Recent availability of proteomic tools allows a large-scale analysis to identify thousands of PTM sites in one experiment by searching mass spectrometric data against the sequences of the genome-wide encoded proteins. The large-scale identification of PTM sites is carried out by a combination of the enrichment of specific modified proteins/peptides and mass spectrometric analysis (Figure 7). For identification of acetylation in proteins, pan-antibodies (antibodies recognized modified amino acids or peptide) against acetylated peptides have been developed to enrich acetylated peptides. However, investigations into functions and regulations of a specific PTM are still needed.

Phosphorylation of proteins, predominantly at histidine residues, is a common mechanism of signal transfer in 'two-component' regulatory systems, such as that described for chemotaxis above. Stimulation of the surface receptor, Mcp, induces a phospho-relay system through several chemotaxis (Che) proteins, leading eventually to signaling the flagellar motor to rotate or not. Although histidine phosphorylation was discovered 50 years ago and was functionally important in central metabolism and bacterial cell signaling, the large-scale analysis of protein histidine phosphorylation is a difficult task due to the acid labile nature of the phosphohistidine residue. Recently, pan anti-phosphohistidine antibodies have been developed and successfully applied into immuno-detection and identification of histidine-phosphorylated proteins.

Phosphorylations at Ser/Thr/Tyr residues have been extensively characterized in different bacterial species. In *E. coli*, 81 phosphorylation sites from 79 proteins were identified with distribution of Ser/Thr/Tyr phosphorylation sites 68%/23%/9% respectively. In *Mycobacterium tuberculosis*, 516 phosphorylation sites were identified from 301 proteins. PknG, one of the 11 Ser/Thr protein kinases encoded by the *Mycobacterium tuberculosis* genome, has been extensively studied for its function and regulation. The autophosphorylation of PknG mediates the survival of pathogenic mycobacteria in host macrophages.

Tyrosine phosphorylation in bacteria is regulated by tyrosine kinases containing Walker A and B motifs and phosphatases including the eukaryotic-like phosphatases (PTPs), dual-specific phosphatases and the low molecular weight protein-tyrosine phosphatases (LMW-PTPs). In *E. coli*, both tyrosine kinase Wzc and phosphotyrosine-protein phosphatase Wzb are involved in exopolysaccharide synthesis, and in turn regulate pathogenicity of bacteria. Wzc also possesses an ATPase activity regulated by autophosphorylation. Quantitative phosphoproteomics has also been applied to characterization of the dynamics of the *E. coli* phosphoproteome showing that a global increase of protein phosphorylation levels occurs in late stationary phase.

Protein acetylation can occur at amino groups of the protein N-terminus or lysine residues, so called protein N-acetylation. Unlike the prevailing existence of protein N-terminal acetylation in eukaryotes, protein N-terminal acetylation was rarely observed in prokaryotes. Three N-terminal acetyltransferases in *E. coli*, Rime, RimJ and RimL, specifically modify ribosomal proteins S18, S5 and L12, respectively. The level of N-terminal acetylation is correlated with the growth phase in *E. coli*. Until

Figure 7 Proteomic workflow for identification of protein post-translational modifications. Proteins from bacterial samples are enzymatically digested; peptides with a specific modification enriched by affinity chromatography, followed by analysis with nano-flow chromatography coupled with tandem mass spectrometry.

recently, only a few acetylation events were observed in bacteria. Proteomic analysis has greatly increased the number of acetylation sites identified. Using a combination of immunoprecipitation and mass spectrometry analysis, hundreds of acetylation sites have been identified in *E. coli* and in *Salmonella*. Proteins targeted by lysine-acetylation mediate a variety of cellular processes. For example, acetylation of the chemotaxis response regulator CheY decreases its binding to the promoters of the targeted genes.

Protein acetylation plays a crucial role in regulation of cellular metabolisms. Many metabolic enzymes are acetylated mostly by Gcn5-related N-acetyltransferases (GNATs). Pat/YifQ, one of the extensively characterized GNAT in *Salmonella enterica* negatively regulates acetyl-CoA synthetase activity once it is acetylated at Lys609. Deacetylation of acetyllysine residues in proteins is carried out by sirtuin-like NAD-dependent deacetylases. CobB, the best-characterized sirtuin in bacteria, plays important roles in regulation of cellular metabolism. One of the best-characterized substrates of CobB is acetyl-CoA synthetase. Acetylation of acetyl-CoA synthetase inhibits its activities but the deacetylation by CobB reactivates the activities of acetyl-CoA synthetase. Acetylation and deacetylation of ribosomal proteins have been reported, suggesting acetylation may have a role in protein synthesis in bacteria.

Concluding Remarks

It will not have escaped the reader's attention that although there are modifications in DNA, RNA, and protein in *E. coli*, we know little about their functions. Some progress has been made for N^6 -methyladenine in DNA in Enterobacteria but not for the more widespread cytosine methylated bases. In heavily modified RNA, we have only a vague notion as to their function. Protein phosphorylation relay systems are well established but other modifications have only been studied in sporadic instances. Research into the modification of polymers would seem to be a fertile field given all these unknowns. It is probable, however, that future insights into the role of these modifications will come from two areas other than traditional fundamental research in *E. coli*. The first is from other bacteria through computational comparative genomics of sequenced genomes where open reading frames encoding conserved predicted proteins with amino acid motifs and/or folds associated with binding of co-factors (such as SAM) identify potential modification enzymes. The second is through research on bacteria of medical, commercial, or environmental importance since it is in this area that most current research is focused. The rapid development of genomics and proteomics technologies has made it possible to identify chemical modifications on nucleic acids and proteins in a high throughput manner. The next challenge is to uncover the biologic meanings of these modifications.

Defining Statement

Microbial adhesion is crucial to the survival and lifestyle of many microorganisms. Both beneficial and pathogenic relationships forged between microbe and host depend on adhesive events and colonization. This article highlights the highly evolved microbial adhesion mechanisms and discusses the prevalence and implications of adhesion in diverse ecosystems.

Introduction

From the center of the earth and deep-sea vents to plant roots and the human intestine, microorganisms occupy remarkably diverse niches on our planet. These microbes include bacteria, archaea, fungi, and protista, and are found attached to rocks and soil particles, corals, and ocean sponges. Bacteria, for example, symbiotically colonize plants and humans as well as fish and squid, resulting in mutual benefit to both microbe and host. Pathogenic and unwelcome bacteria can egress from their native niche and adhere to and infect other sites and host tissues, leading to cellular injury and disease. Microbes also adhere to the hulls of ships and to machinery in food processing factories, resulting in contamination and adverse circumstances. Specific adhesion strategies have evolved in order to facilitate microbial attachment to diverse substrata in both symbiotic and pathogenic associations. Understanding the molecular mechanisms and functional implications of microbial adhesion is crucial for generating complete descriptions of our ecosystems, understanding and predicting ecosystem stability due to globalization and climate change, and attempting to control and prevent the unfortunate and often devastating consequences of infectious diseases. Thus, microbial adhesion is a fundamental component of the field of microbial ecology. This article will focus on the adhesive strategies employed specifically by bacteria, though many parallels can be found in the arsenal of adhesive strategies harbored by the other classes of microbes. We will highlight several exciting and up-to-date scientific discoveries as a platform to illustrate the biological significance and implications of microbial adhesion.

Biological Significance of Microbial Adhesion

The propensity for bacteria to associate with surfaces (living or abiotic) in nearly all ecosystems far exceeds the tendency to persist in suspension, living freely in a planktonic state. Attachment to surfaces allows bacteria to persist in advantageous locations where there may be high nutrient concentrations or to provide protection from hostile environments. In numerous instances, bacteria form biofilms – structurally complex and dynamic bacterial communities. The metabolic labor of acquiring nutrients is divided, sometimes according to spatial coordinates in the community, and distribution is promoted through an organized architecture of community members. Protection from harsh environmental conditions is a major benefit of life in a biofilm and the first line of defense is provided by members residing at the edges of the community. Under certain conditions, bacteria disperse from the biofilm, to seek a new environment and potentially re-adhere and colonize new niches. Adhesion events are crucial to biofilm formation, growth, and development. We set the stage for discussing the mechanisms of microbial adhesion by first illustrating a few examples across a broad landscape in which bacterial adhesion (often followed by biofilm formation) takes place.

Adhesion in the Water

The coral reefs are home to an enormous diversity of marine life, including charismatic and commercially important species of fish, mollusks and urchins, and the significantly smaller microorganisms with which they cohabit. Bacteria are, in fact, an integral constituent of the microbiota of healthy corals. They colonize distinct sites in coral tissue including the surface mucous layer and porous components in the coral skeleton where they fix nitrogen, decompose chitin, and provide organic compounds. The molecular mechanisms of adhesion and the sustained interactions between bacteria and their coral hosts are currently not well understood but are key questions being addressed in the emerging field of coral microbiology. Understanding the microbial interactions that promote health versus those that cause disease is important in efforts to preserve and prevent further destruction of coral reefs worldwide. Adhesion of bacteria in many water environments inevitably has detrimental consequences. Bacterial adhesion and biofilm formation on the hulls of ships creates resistance to water flow, increases drag, and thus decreases the efficiency of movement through the water. Microbial fouling is an economic and environmental burden in this way and in several industrial settings including drinking water pipes and oil pipelines, where the proliferation of sulfide-producing bacteria leads to the

This article is an update of L. Cegelski, C.L. Smith, S.J. Hultgren, Adhesion, Microbial, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 1–10.

deterioration and corrosion of the steel surfaces. Understanding the mechanisms of adhesion is key to developing strategies to control and prevent these adverse and costly consequences.

Adhesion to Plants

Rhizobia are Gram-negative soil bacteria that adhere to and colonize the root cells of leguminous plants, including soybeans and alfalfa. Upon entry into a root hair, rhizobia traverse a distance to the center of the root hair cell and together with proliferating plant cells form a nodule. Here, rhizobia fix nitrogen, converting molecular nitrogen (N₂) from the air into ammonia, nitrates, and other nitrogenous compounds to support plant metabolism. Rhizobia are particularly important to plants in nitrogen-deficient soils. In return, rhizobia receive carbon rich organic compounds, important for their own energy production, from the plant. Other beneficial symbionts include *Bacillus thuringiensis*. This bacterium is an important Gram-positive pathogen whose insecticidal properties have gained attention in the development of crops genetically modified to express the bacterium's potent toxin, now referred to as Bt transgenic crops. In the wild, *B. thuringiensis* colonizes the surface of some plants and exists naturally in some caterpillars. The bacterium produces a unique kind of endotoxin, a proteinaceous crystal that is lethal to several pests, including flies, mosquitoes, and beetles, upon ingestion. This symbiosis with plants is dependent on initial host–microbe adhesion events. The attractive chemical signals and ultimate adhesive interactions of *Agrobacterium tumefaciens* with wounded plants leads to the unfortunate development of tumors on the lower stems and main roots, the hallmark of Crown Gall diseases. Attachment is the first step in the pathogenic cascade and takes place in the soil around the roots –the rhizosphere. In a two-step adhesive process, initial weak binding interactions are followed by the bacterial expression of multiple gene products to synthesize cellulose and anchor the microbe to the host tissue, while enhancing adhesive interactions between bacteria in the microcolony. Adhesive plant proteins called vitronectins are also implicated in the adhesion process. Subsequent DNA transfer and integration of a specific fragment of DNA (the transfer DNA) from the bacterium to a plant cell results in the expression of several oncogenic genes and the formation of tumors.

Adhesion in the Human Host

The normal and healthy human body is composed of approximately ten times more bacterial cells than human cells. These bacteria comprise our microbiota and are colonized in distinct sites throughout the body, including the skin and mouth, the small intestine, and colon. In the mouth and small intestine, bacterial adhesion is critical to maintenance of microbial populations, where either salivary flow or movement of contents eliminates the nonadherent bacteria. Our microbiota is, in general, beneficial; for example, bacteria in the gut degrade some otherwise indigestible polysaccharides into carbon and energy sources. Recent results indicate that the balance of bacterial populations in the gut influence caloric intake through complex interbacterial metabolic networks and further study may help to understand and potentially control (decrease or increase) caloric uptake. Indeed, the microbiota is dynamic and shifts in balance that alter the relative numbers of different bacterial populations can also lead to proliferation of disease-causing opportunistic pathogens. In addition, the inoculation of the human host with bacteria from the environment is a common source of infectious disease, particularly in the hospital setting. The consequences of bacterial adhesion in human infectious diseases are numerous and will be addressed in more detail after the description of specific adherence mechanisms.

Mechanisms of Microbial Adhesion

General Physicochemical Factors Affecting Adhesion

Mechanisms of microbial attachment are incredibly diverse and can be generally classified as either general nonspecific interactions or specific molecular-recognition binding events that involve the presentation of specific adhesive proteins on the bacterial cell surface. Of course, multiple mechanisms can act cooperatively to promote adhesion. A successful adhesive event depends on properties of both the bacterium and the substratum. Nonspecific interactions are the primary form of attachment to abiotic surfaces in aquatic and soil environments. Van der Waals interactions are attractive, usually weak, noncovalent forces that can operate at large separation distances (>50 nm) between the bacterium and the surface. At smaller distances (10–20 nm), electrostatic interactions participate and compete as attractive and repulsive forces. The net surface charge of most bacteria is negative due to cell wall and cell membrane components including negatively charged phosphate groups, carboxyls, and other acidic groups, in addition to surface-exposed proteins. Thus, bacteria like to adhere to positively charged surfaces. Typical binding surfaces, however, have a net negative surface charge, creating electrostatic repulsion that must be overcome by other physicochemical factors. The entire binding process is akin to a tug-of-war. The ionic strength of the surrounding medium affects the electrostatic interactions, and the aforementioned repulsion is eliminated, for example, in most aquatic environments due to high ionic strength resulting from high salt concentration. In the range of near contact (0.5–2 nm), hydrophobic interactions are important for bacterial adhesion. Energetically, the association of nonpolar groups on a bacterial surface with hydrophobic surfaces compensates for the unfavorable displacement of water molecules at that surface. When separated by less than 1 nm, stronger interactions including hydrogen bonding and the formation of salt bridges contribute to surface adhesion.

Specific Adhesin–Receptor Mechanisms

On many biotic surfaces, the adhesive forces and interactions described above promote the formation of an initial interface, but require concomitant or subsequent specific adhesive interactions to enable firm adhesion. Adhesin is the term ascribed to the surface-exposed bacterial molecule that mediates specific binding to a receptor or ligand on a target cell. It is not unusual for bacteria to harbor several types of specific adhesive machinery to provide adhesive capacity to multiple receptor molecules or to permit adhesion under changing environmental conditions such as temperature, pH, or nutrient status, where one adhesive strategy may be more effective than another. Bacteria can produce a diverse array of adhesins with varying specificities for a wide range of host receptor molecules. Adhesion mechanisms can be classified according to the type of adhesin–receptor pair. Many bacterial adhesins function as lectins and the interactions between bacterial lectins and host cell carbohydrates are among the best-characterized attachment processes. Hallmark examples of carbohydrate recognition include *Pseudomonas aeruginosa*, *Haemophilus influenzae*, and *Streptococcus pneumoniae* adhesion in the respiratory tract, *Escherichia coli* adhesion in the urinary tract and intestine, and *Helicobacter pylori* adhesion in the stomach. Other adhesins recognize specific amino acid-recognition motifs in proteins expressed on host cell surfaces. Extracellular matrix (ECM) proteins that are not directly integrated into the host cell also serve as attractive binding platforms for many bacteria, such as *Enterococcus faecalis* and *Staphylococcus aureus*, and numerous adhesins bind to these components in order to indirectly hijack the host signaling pathways, often to enable host cell internalization. Another general category of adhesins includes nonproteinaceous molecules such as lipopolysaccharides and teichoic acids, synthesized by Gram-negative and Gram-positive bacteria, respectively.

Most adhesins are incorporated into heteropolymeric extracellular fibers called pili or fimbriae. Bacteria invest enormous cellular resources to assemble fimbriae in order to present adhesins at the right time and the right place to initiate attachment when conditions are favorable and to permit detachment when necessary. Indeed, hundreds of such fibers have been described in Gram-negative organisms, and although they have diverse functions, many appear critical to binding, invasion, and survival of pathogenic microorganisms in the human host. Distinct assembly mechanisms have emerged as the most well studied and include the chaperone–usher pathway (CUP pili), the general secretion pathway (type 4 pili), the extracellular nucleation–precipitation pathway (curli), and the alternate chaperone pathway (class 5 pili). Gram-positive pathogens also produce adhesive pili. Unlike their Gram-negative counterparts, Gram-positive pili are formed by covalent polymerization of pilin subunits, for example the endocarditis and biofilm-associated pili (Ebp) from *E. faecalis* and Pilus Island 1 (PI-1) from *S. pneumoniae*. A representative set of fimbrial adhesins is provided in Table 1 for Gram-negative and Table 2 for Gram-positive.

Table 1 Representative Gram-negative fimbrial adhesins, adhesins, and disease association

Organism (s)	Adhesin	Assembly proteins	Associated fiber	Associated disease(s)

Some bacteria present afimbrial adhesins on their surface, including Staphylococcal species, which solely use afimbrial adhesive factors and do not encode pili. Afimbrial adhesins are expressed as monomeric proteins or protein complexes that assemble at the cell surface and recognize host cell surface elements. Staphylococci have a variety of cell wall bound adhesins that binds a number of host factors, including fibrinogen and fibronectin. These adhesive factors are essential for infective endocarditis, systemic infection, and kidney abscess formation. *E. faecalis* also has a number of adhesins such as Ace, ElrA, and Esp; for example, Ace binds to collagen and laminin and important during UTI and endocarditis. Adhesive autotransporters represent a class of afimbrial adhesins expressed by a variety of unrelated microorganisms, including species of *Rickettsia*, *Bordetella*, *Neisseria*, *Helicobacter*, and many members of the family Enterobacteriaceae. *H. influenzae*, a causative agent of sinusitis, bronchitis, otitis media, and pneumonia, expresses an adhesive autotransporter termed Hap. Hap mediates binding to laminin, fibronectin, and collagen, all components of the ECM.

The most comprehensive descriptions of bacterial adhesion have emerged from studies of pathogenic bacteria involved in infectious diseases. Examples of these host–microbe interactions as well as some involved in the attachment of bacteria to plants, either as symbionts or as pathogens, are described in more detail below to highlight the remarkable diversity, specificity, and complexity among microbial adhesive strategies.

Selected Survey of Specific Adhesion Strategies

Pilus-Mediated Adhesion to Carbohydrates in the Urinary Tract

Uropathogenic *E. coli* (UPEC) colonize the gut as well as the genitourinary tract and produce numerous important adhesins and adhesive CUP pili organelles to mediate adhesion in these niches. A recent analysis of 35 *Escherichia* spp. genomes and 132 plasmids identified a total of 458 CUP operons, representing 38 distinct CUP pilus types based on usher phylogeny. Single *Escherichia* genomes can have as many as 16 distinct, intact CUP operons encoding adhesins with stereochemical specificity for their ligands, which have important influences on microbial tropisms. For example, FimH and PapG adhesins are presented at the tips of type 1 and P pili, respectively. FimH-presenting type 1 pili are required for *E. coli* to cause cystitis, or infection of the bladder, and PapG presenting P pili are associated with pyelonephritis, infection of the kidney. Type 1 and P pili are composite heteropolymeric structures, with a distal tip fibrillum joined to a thicker rigid helical rod and both are assembled by the chaperone–usher system. These systems are prototypes for the 100's of chaperone–usher systems that have been identified through comparative genome analyses of pathogens including *E. coli*, *Salmonella*, *Haemophilus*, *Klebsiella*, and *Yersinia*.

In each chaperone–usher system, pilus assembly requires a unique assembly protein pair (a chaperone and a usher) to facilitate the folding, transport, and ordered assembly of pilus subunits at the cell surface. This process begins in the periplasm after subunit expression and translocation by the general secretory pathway into the periplasm. Periplasmic pilus chaperones consist of two immunoglobulin (Ig)-like domains and bind to and assist folding of subunits to keep their interactive surface capped and prevent nonproductive subunit aggregation. Pilin subunits also have an Ig-like fold, but they lack the seventh β strand, thus exposing the hydrophobic core. In a process termed donor strand complementation, the chaperone's G1 β -strand serves as the pilin's seventh strand, catalyzing the folding of the subunit. Chaperone–subunit complexes are targeted to their cognate outer membrane usher to facilitate chaperone uncapping, translocation of subunits across the outer membrane, and pilus assembly. Each cognate usher consists of five functional domains: a 24 stranded transmembrane β -barrel translocation domain (TD), a β -sandwich plug (PLUG) that resides in the pore of the TD in the apo-usher, an N-terminal periplasmic domain (NTD) and two C-terminal periplasmic domains (CTD1 and 2). Binding of the chaperone–adhesin complex to the usher's NTD results in the PLUG domain being translocated into the periplasmic space and a conformational change in the TD from the apo, kidney shaped conformation (52 x 28 Å) to a circular form (44 x 36 Å). This conformational change likely facilitates the extrusion of folded pilins (~20–25 Å in diameter) across the outer membrane. After translocation into the periplasmic space the PLUG domain mediates a high affinity interaction with the NTD of the usher. Thus, the PLUG

Figure 1 The FimH adhesin and type 1 pili-mediated adhesion of *E. coli*. (a) The ribbon representation of FimH (from the crystal structure of the FimCH complex). D-mannose is located at the top of the molecule. (b) Molecular surface representation in which the electrostatic potential surface with positively charged residues is shown in blue, negatively charged residues in red, and neutral and hydrophobic residues in white. Residues defining the hydrophobic ridge around the mannose-binding pocket are labeled. (c) The mannose-binding site with FimH residues. Mannose residues are shown with carbon atoms in yellow, oxygen atoms in red, and nitrogen atoms in blue. (d) Type 1 pili-mediated attachment of uropathogenic *E. coli* (UPEC) to the luminal surface of the bladder epithelium. (Top) High-resolution, freeze-fracture, deep-etch electron micrograph is from Mulvey MA, Lopez-Boado YS, Wilson CL, *et al.* (1998) Induction and evasion of host defenses by type 1-piliated uropathogenic *E. coli*. *Science* 282: 1494–1497. Reprinted with permission from AAAS. (Bottom) Scanning electron micrograph of a bacterium entering the membrane of bladder epithelial cells is reprinted from Soto GE and Hultgren SJ (1999) Bacterial adhesins: Common themes and variations in architecture and assembly. *Journal of Bacteriology* 181: 1059–1071.

gates the TD, such that in the absence of pili the PLUG prevents large molecules from flowing freely across the outer membrane. The PLUG, the NTD, CTD1 and CTD2 work together in the assembly function of this molecular machine. This occurs via a process termed donor strand exchange, in which the G1 β -strand of the chaperone is replaced by an N-terminal extension of the next pilus subunit. Thus in the mature pilus, each subunit incorporates its neighbor's N-terminal extension as part of its own Ig fold. Subunits have distinct specificity for other interactive subunits and distinct roles in pilus adhesion, initiation, elongation, termination and regulation.

The FimH adhesin, incorporated at the tip of the type 1 pilus, consists of a pilin subunit and the receptor binding domain (Figure 1). The primary carbohydrate specificity of FimH is mannose. Interestingly, different *E. coli* isolates present FimH variants (specific allelic variations in protein sequence and structure) that exhibit varying specificities for monomannose and trimannose binding. FimH expressed by most commensal isolates of the intestine exhibit a higher specificity for trimannose presenting glycoprotein receptors, whereas urinary tract isolates encode for a FimH variant with higher affinity for monomannose. In the latter, FimH mediates adhesion to the monomannose-containing glycoprotein uroplakin Ia that is expressed on the surface of superficial facet cells –the epithelial cells that line the lumen bladder (Figure 1). Further, the FimH sequences of uropathogenic *E. coli* strains (UPEC) have invariant mannose binding pocket residues; however, there are some residues outside of the binding pocket that are under positive selection in clinical UPEC isolates that influence mannose binding by influencing a conformational switch. FimH can adopt two conformations, compact and elongated, and switch between them, and the allelic variation of these residues can favor one state or another. The elongated conformation has high mannose binding ability, which is important for binding to the mannoseylated-urothelial cells; while the compact form has low mannose binding ability. However, recent studies have shown that FimH variants, that maintain the elongated conformation and appear unable to effectively switch between conformations, were attenuated during chronic bladder colonization arguing that switching between conformations is important for *E. coli* pathogenesis in the urinary tract. Presented at the tips of P pili, the PapG adhesin mediates binding to a different carbohydrate receptor, the α -D-galactopyranosyl-(1–4)-D-galactopyranoside moiety of glycolipids presented by cells predominantly in the kidney. PapG variants (G-I, G-II, and G-III) exhibit altered specificities for three Gal α (1–4)Gal-containing isoreceptors: globotriaosylceramide, globotetraosylceramide (GbO4), and globopentaosylceramide (the Forssman antigen). The demonstrated allelic variation in PapG and FimH binding specificities supports the notion that, through bacterial evolution, pathoadaptive mutations are selected for increasing the fitness of pathogenic organisms in distinct niches in the host.

Adhesion to ECM Components

The ECM contains a diverse array of oligosaccharides, proteoglycans, and proteins and functions to provide structural support and adhesive interactions among cells. Prevalent components include collagen, fibrinogen, fibronectin, laminin, and vitronectin, as well as molecules such as heparin sulfate and chondroitin sulfate. Fibronectin is present in most tissues and fluids of the body and helps to create a cross-linked network between cells by presenting binding sites for other ECM components, a process that pathogenic organisms exploit to gain a foothold in host tissue. The ability to adhere to ECM components is a primary adhesion mechanism that contributes to the virulence of many pathogenic microorganisms. *S. aureus* is a significant cause of nosocomial and often persistent infections. Among other ECM-binding proteins, *S. aureus* expresses the fibronectin-binding proteins FnBP-A and FnBP-B that permit adherence to fibronectin that are bridged to cellular integrins. This crucial binding event leads to host cell cytoskeletal rearrangements and invasion. *Streptococcus pyogenes* is armed with more than 12 fibronectin- and collagen binding proteins. Like the FnBP-A adhesin in *S. aureus*, the major *S. pyogenes* adhesin, SfbI, and the *Yersinia* adhesin, YadA, bind to fibronectin and bridge the bacteria to integrins, leading to integrin clustering and eventual internalization. Fibrinogen is present in tissues and fluids throughout the human body and helps control proper blood homeostasis through clotting. Clotting, or blood coagulation, is a tightly controlled process initiated during injury or infection through the release of specific signals that activate the host protein thrombin. Thrombin then cleaves soluble fibrinogen into insoluble fibrin cables creating clots. *S. aureus* encodes numerous adhesin proteins that bind fibrinogen and fibrin cables, including clumping factor A and B (ClfA and ClfB), which are essential during initiation and establishment of infection. Additionally, *S. aureus* is able to circumvent the tightly controlled clotting cascade through the secretion of proteins that induce cleavage of fibrinogen to fibrin cables, providing a substrate for ClfA and ClfB to bind and establish infection at almost any body site. Similar to the most of staphylococcal surface adhesins, ClfA and ClfB are covalently linked to the cell wall by the housekeeping membrane-bound transpeptidase sortase A (SrtA). These adhesins contain a C-terminal LPXTG motif that is recognized and cleaved by SrtA between the threonine and glycine and the carboxyl group of threonine is then covalent linked to the amino group of peptidoglycan cross-bridges.

Similar to *S. aureus*, *E. faecalis* also binds to fibrinogen via Ebp pilus and this interaction is important for establishing a catheter-associated urinary tract infection and for binding to platelets. The Ebp pilus is composed of three structural proteins, EbpA (tip), EbpC (shaft) and EbpB (base), and its assembly and anchorage to the cell wall is dependent two sortases, SrtC (pilus-associated) and SrtA, respectively. All three subunits contain a LPXTG motif, which plays an important role for their incorporation and additionally, EbpC and EbpB contain a pilin-like motif, which important for polymerization of the pilus fiber. The pilin motif is located in the N-terminal domain of the protein and contains a lysine residue that is involved in the formation of an intermolecular bond between of an incoming subunit and the threonine residue of the LPTXG of the recently incorporated subunit. EbpA is the first subunit to be incorporated by SrtC, which cleaves the LPXTG motif and linked to the pilin motif Lys residue of EbpC and this step is followed by EbpC polymerization, which is mediated by SrtC. After polymerization of EbpC, EbpB, the base subunit, is incorporated into the growing fiber via its pilin motif, and then SrtA anchors the fully polymerized pilus fiber into the cell-wall.

Contrary to the previous examples, *Yersinia* has an adhesin, invasin that bypasses the ECM and binds directly to integrin transmembrane receptors. Other less-ubiquitous ECM components also serve as binding receptors for bacterial adhesins and their sites of expression often relate to the tissue tropism of a particular bacterial pathogen.

Curli-Mediated Multipurpose Adhesion

Curli are a unique class of adhesive extracellular amyloid fibers produced by Gram-negative bacteria, including *E. coli*. The highly homologous fibers produced by *Salmonella* species are called Tafi (thin aggregative fimbriae). The fibers mediate biofilm formation and attachment to host proteins including fibronectin, laminin, and plasminogen, and have been implicated in human sepsis. When expressed together with cellulose, curli and Tafi contribute to a remarkable aggregative phenotype characterized by a patterned assembly of cells radiating from the center when grown on a surface such as agar. Curli are assembled by the nucleation–precipitation pathway, and assembly requires specific molecular machinery encoded by the *csgBA* and *csgDEFG* operons (Figure 2). The major subunit protein (CsgA) and the nucleator protein (CsgB) are secreted to the cell surface in a CsgG dependent fashion. CsgE and CsgF are assembly factors required for the stabilization and transport of CsgA and CsgB. Transcriptional regulation of the curli operons is complex and responds to many environmental cues including temperature, pH, and osmolarity. The adhesive functionality is attributed to the main fiber subunit, CsgA. Curli are also implicated in the binding of *E. coli* strains to plant surfaces and are expressed by many strains associated with food-borne illness, including the prototype strain *E. coli* O157:H7, which has caused several foodborne outbreaks in the United States and around the world. Although the exact nature of binding is still under investigation, curli production is sufficient to permit laboratory strains of *E. coli* to bind plant tissues, such as alfalfa. However, among pathogenic strains such as *E. coli* O157:H7, there appear to be redundant adhesion systems, and under the conditions tested, curli are not required for adhesion. Indeed, external conditions in the environment and in the host may differ as a function of time, and bacteria may depend more on one adhesive system than another in certain circumstances.

The curli bacterial adhesive fiber machinery has gained considerable attention since the discovery of curli as amyloid fibers in 2002. The sticky nature of curli amyloid fibers is like that of amyloid aggregates and plaques associated with eukaryotic amyloid

Figure 2 Curli biogenesis and biology. (a) Current model of curli biogenesis. Curli assemble through the nucleation–precipitation pathway. Polymerization of the major curli subunit protein, CsgA into β -sheet-rich amyloid fibers depends on the nucleating activity of the minor subunit, CsgB. Proteins CsgE, CsgF, and CsgG are assembly factors required for the stabilization and transport of CsgA and CsgB to the cell surface. (b) Congo red-binding phenotype. Curli are amyloid fibers and bind the hallmark amyloid dyes Congo red and thioflavin T. Curliated *E. coli* grown on Congo red-containing agar medium take up the dye and stain red. Noncurliated cells do not. (c) High-resolution deep-etch electron micrographs of curliated *E. coli*. From Chapman MR, Robinson LS, Pinkner JS, *et al.* (2002) Role of *Escherichia coli* curli operons in directing amyloid fiber formation. *Science* 295: 851–855. Reprinted with permission from AAAS.

disorders such as Alzheimer's and Parkinson's diseases. Thus, ongoing curli research that aims to elucidate structural features of curli assembly and the functional implications of curli-mediated adhesion may also provide valuable information to the exciting field of amyloid fiber biogenesis and aggregation.

Consequences of Microbial Adhesion in Human Disease

The critical first step in most infectious diseases requires physical contact between a bacterium and host cell. Bacterial adhesins mediate this binding event through the sophisticated adhesion mechanisms described above and allow the pathogen to gain a foothold in the host, initiating complex signaling cascades in both the pathogen and the host. Binding events can lead to extracellular colonization and invasion into underlying host cells. Adhesion is the first step that promotes the cascading sequelae of infectious diseases, particularly important in the pathogenesis of chronic infections including urinary tract infection (UTI), chronic otitis media (middle ear infection), and chronic lung infections.

E. coli and UTI

UPEC engage in an incredibly coordinated and regulated genetic and molecular cascade to assemble type 1 pili, as described above. UTIs are among the most common bacterial infections and nearly 50% of women will be afflicted by at least one UTI in their lifetime, with many experiencing recurrent UTIs. Virtually all clinical UPEC isolates express type 1 pili, enabling them to bind the mannose-containing host receptors, which results in invasion of host bladder epithelial cells (Figure 3). Once inside the epithelial cells, UPEC is protected from innate immune defenses of the host, and a single bacterium can replicate to 10^4 or more bacteria within hours, forming intracellular bacterial communities (IBCs) that have biofilm-like properties. IBCs are transient in nature and upon maturation, bacteria from the IBC subsequently become filamentous as they disperse from the biomass and spread to neighboring host cells where they repeat the cycle. IBC formation is a general trait of UPEC and IBCs and the filamentous UPEC that emerge from them are significantly observed in urines from women with rUTI but not healthy controls, or in patients with a UTI caused by Gram-positive pathogens. Population dynamic studies revealed a strict bottleneck in acute infection. From an initial 10^7 inoculum, only $\sim 10^4$ UPEC invade the bladder tissue after infection and only one percent of those invaded bacteria go on to form

Figure 3 Pathogenic cascade of uropathogenic *E. coli* (UPEC). UPEC coordinate highly organized temporal and spatial events to colonize the urinary tract. UPEC bind to and invade the superficial umbrella cells that line the bladder lumen, where they rapidly replicate to form a biofilm-like intracellular bacterial community (IBC). In the IBC, bacteria find a safe haven, are resistant to antibiotics, and subvert clearance by innate host responses. UPEC can persist for months in a quiescent bladder reservoir following acute infection, and challenge current antimicrobial therapies. Quiescent bacteria can reemerge as pathogens from their protected intracellular niche and can be a source of recurrent urinary tract infections (UTIs).

IBCs, resulting in an average of 100 IBCs per infected mouse bladder. If this is extrapolated to human infection, this bottleneck likely prevents the majority of bacterial inoculation events into the bladder from leading to disease. However, the finding that a single infecting bacterium can replicate clonally within hours to 10^4 bacteria within a single host epithelial cell and then these bacteria can spread to neighboring epithelial cells to reinitiate the IBC process, suggests that introduction of even a single UPEC bacterium into the bladder can result in a UTI if it transcends the strict bottleneck. In humans, the ultimate outcome of UPEC infection of the UT ranges from asymptomatic bacteriuria to acute self-limiting infection to chronic/recurrent UTI. Placebo studies have shown that 50% of UTIs in humans do not resolve in the absence of effective antibiotic treatment, indicating the importance of clinical intervention for resolution of infection and highlighting the crisis that may ensue as multi-drug resistant pathogens continue to emerge, for example ST131. The outcome of experimental UPEC infection differs among inbred mouse strains, which is reflective of the different disease manifestations observed in humans. For example, in C57BL/6 mice, acute infection and bacteriuria resolves within 7–10 days of the initial infection. In contrast, mice belonging to the C3H and CBA backgrounds are susceptible in an infectious dose-dependent manner to long-lasting, chronic cystitis characterized by (i) high titers ($>10^4$ CFU) of bacterial burdens in the bladder tissue and persistent high titer bacteriuria ($>10^4$ CFU/ml) throughout infection; (ii) ongoing acute and chronic inflammation in the bladder, which prevents regeneration of the superficial facet cell layer; and (iii) a predisposition to severe rUTI upon subsequent bacterial challenge even months after antibiotic treatment to clear the initial chronic infection. In C3H mice, the induction of high levels of serum cytokines (IL-6, IL-5, G-CSF) and neutrophil chemokines (CXCL1 and CXCL2) at 24 hpi, is predictive of severe chronic cystitis.

P. aeruginosa and CF

P. aeruginosa has emerged as an opportunistic pathogen in several clinical settings, causing nosocomial infections such as pneumonia, UTIs, and bacteremia. *P. aeruginosa* adheres to the respiratory epithelium, leading to chronic lung infections in cystic fibrosis (CF) patients, responsible for the eventual pulmonary failure of most CF patients, typically by 37 years of age. Pilus-mediated adherence is important in the adhesion and early stages of epithelial colonization, and additional virulence factors contribute to the subsequent persistence in the lung. Alginate, for example, is a mucoid exopolysaccharide produced by *P. aeruginosa* that forms a matrix of 'slime' to surround a forming biofilm and anchors the cells to each other and to their host. Surrounded by alginate, the bacteria are protected from the host defenses and are often resistant to treatment with antibiotics.

S. aureus and Invasive Infections

S. aureus is an important human pathogen responsible for causing a wide range of invasive infections, including necrotizing pneumonia, bacteremia, infective endocarditis, shock following bacteremic UTI, among many other infections. *S. aureus* is able to establish such a wide range of infections because this pathogen encodes numerous adhesins, termed Microbial Surface Components Recognizing Adhesive Matrix Molecules (MSCRAMMs) that allow *S. aureus* to adhere to many different underlying host tissues and ECM proteins, including platelets, fibrinogen, fibronectin, and collagen. Interactions between *S. aureus* and ECM proteins allow the bacteria to form different types of community structures, including biofilm and agglutinates, which are important for establishment and persistence of disease. Biofilms form when *S. aureus* adheres to surfaces and develops attached communities that enable the bacteria to persist during infection. *S. aureus* biofilms are particularly problematic during implant-associated infections such as those that can form on pace-makers, central lines, and prostheses, which are recalcitrant to treatment. These implants are typically coated with host ECM proteins upon implantation, providing a substrate for bacterial attachment and biofilm formation. Agglutination refers to the process by which individual bacteria interact through adhesin-ECM protein bridges creating tightly packed communities that can remain unattached to surfaces. These communities form in the absence of a traditional endothelial or epithelial substratum, such as in the blood stream or other body fluids, where high local concentrations and accessibility of ECM proteins provide a binding substrate for *S. aureus* adhesins. Agglutination in *S. aureus* occurs via interactions between the ClfA adhesin and the host ECM protein fibrinogen. ClfA specifically binds fibrinogen via the δ domains exposed on either end of the matrix protein, effectively linking fibrinogen to the cell surface. Two ClfA proteins binding δ domains on the same fibrinogen protein creates an ECM bridge and induces agglutination. The general ability of *S. aureus* to form tightly packed groups of cells aids survival in various host situations and these communities rely on adhesive protein interactions with host. ClfA is also an important immune modulator making this adhesin protein particular important for initiation and persistence of disease.

E. faecalis UTI and CAUTI

E. faecalis is able to cause ascending UTI and is a frequent causative agent of catheter-associated UTIs (CAUTI), and if untreated, can lead to serious complications including bacteremia and death. Urinary catheterization by itself causes histological and immunological changes in the bladder due to mechanical stress, resulting in a robust inflammatory response and edema of the lamina propria and submucosa, and mucosal lesion of the urothelium and kidney. Fibrinogen is released as part of the inflammatory response and accumulates in the bladder lumen, coating the urinary catheter. *E. faecalis* takes advantage of the availability of fibrinogen and uses it as bridge to form biofilm on the catheter. The interaction between *E. faecalis* and fibrinogen is mediated by the Ebp pilus adhesin, EbpA, which is important for establishment and persistence during CAUTI. Moreover, disruption of this interaction results in protection of the host.

Targeting Adhesion to Inhibit Bacterial Virulence

The ability to impair bacterial adhesion represents an ideal strategy to combat bacterial pathogenesis because of its importance early in the infectious process. In addition, adhesion is essential to the long-term persistence of bacteria in the pathogenic cascade of several infectious diseases. Moreover, the adhesion process can be targeted without placing life or death pressure on the bacterium, per se. Targeting bacterial virulence in this way is an alternative approach to the development of new therapeutics to disarm pathogens in the host that may offer reduced selection pressure for drug-resistant mutations. In addition, virulence-specific therapeutics could avoid the undesirable dramatic alterations of the host microbiota. Indeed, standard antibiotic treatment regimens may lead to the loss of symbiotic benefits and the proliferation of disease-causing opportunistic pathogens. As emphasized earlier, pathogens are capable of presenting multiple adhesins that can be expressed differentially to permit binding in specific sites and at specific times over the course of a complex infectious cycle. Thus, it may be difficult to develop a universal

Figure 4 Targeting microbial adhesion. Rationally designed ‘pilicides’ inhibit pilus biogenesis by disrupting chaperone–usher protein interactions and reduce piliation levels dramatically. Electron micrographs reproduced from Pinkner JS, Remaut H, Buelens F, et al. (2006) Rationally designed small compounds inhibit pilus biogenesis in uropathogenic bacteria. *Proceedings of the National Academy of Sciences of the United States of America* 103: 17897–17902. Copyright (2006) National Academy of Sciences, U.S.A.

class of antiadherence drugs. Nevertheless, several specific pathogenic adhesive strategies have emerged as hallmark requirements for virulence in certain infectious diseases, and represent amenable targets for drug discovery and development. Adhesion is sometimes just the first step of many in pathogenic cycles, yet targeting adhesion holds value even after an infection has been established. In biofilm-associated infections, for example, drug development strategies include attempts to induce the dispersal of bacteria from the biofilm and to inhibit the chemical signaling necessary to encourage new biofilm formation. In UTI, the fluxing bacteria are capable of re-adhering to naïve host cells, gaining a foothold and potentially invading a new cell to remain undetected until drug pressure subsides and conditions encourage replication and new intracellular biofilm formation. Thus, strategies to prevent microbial adhesion are being considered in combination therapies to both prevent and treat infectious diseases. Carbohydrate derivatives of host ligands have demonstrated efficacy in blocking the adhesive properties of *E. coli* expressing type 1 and also P pili in biophysical and hemagglutination assays. This approach of using soluble carbohydrates or mimics recognized by the bacterial lectin can be readily extended to other adherent organisms by tailoring the antiadhesive compounds to their receptor specificities.

'Pilicides' are a class of pilus inhibitors that target chaperone function. A new class of pilicides, based on a bicyclic 2-pyridone scaffold, inhibit the assembly of both type 1 and P pili in *E. coli* (Figure 4). The potent molecules inhibit an essential protein–protein interaction between chaperone and usher, required for pilus biogenesis. Chaperone–usher systems are highly conserved among various bacteria including *Salmonella*, *Haemophilus*, *Klebsiella*, and *Yersinia* and it is possible, although not yet demonstrated, that pilicides may exert broad-spectrum activity and be effective against several Gram-negative pathogens. Compounds have been identified that target the two-component signaling system, AlgR2/AlgR1, that controls the synthesis of alginate by *P. aeruginosa*. Alginate is a key component of the protective exopolysaccharides coat, critical to *P. aeruginosa* adherence, biofilm formation, and CF pathogenesis. The inhibitors of alginate synthesis could be therapeutically employed to render the pathogen more susceptible to host defenses or to standard antibiotics currently in use, and thus could be effective also in combination therapy. The ability to inhibit microbial adhesion and thus prevent subsequent pathogenic processes holds enormous therapeutic potential and promises to improve the treatment of numerous infectious diseases.

Microbial Agents to Treat Cancer

Gil Redelman-Sidi, Memorial Sloan Kettering Cancer Center, New York, NY, United States

Introduction

An association between infection and cancer regression has been recognized for well over a century. In 1853, Sir James Paget, one of the founders of medical pathology, commented on the "... occasional withering of a cancer under the influence of some fever ..." (Onuigbo, 2012). His observations were followed by the recognition, by Louis Pasteur and Robert Koch, of bacteria as the causative agents of infection.

The use of microbes to treat cancer was pioneered by William B. Coley, a surgeon at the New York Hospital, in the late 19th century. Coley noted cases in which tumors regressed after patients developed bacterial skin infections, and he hypothesized that these infections activated the immune system to fight the tumor. To test this hypothesis, Coley injected live cultures of *Streptococcus* into tumors with regression of the tumors in some cases. However, this form of treatment led to development of severe infections in some patients. To address this, Coley began injecting tumors with lysates derived from cultures of *Streptococcus pyogenes* and *Serratia marcescens*. This form of treatment became known as Coley's toxins, and is considered the first example of cancer immunotherapy. Coley's toxins were used in the United States to treat tumors from 1893 to 1963. However, they had mixed success and their use was considered controversial among the oncological community (Coley, 1893; Coley, 1910).

There are three main ways by which Coley's toxins and other forms of microbial-based cancer therapy could work (Fig. 1). First, microbes or their products could be *directly* toxic to tumor cells. Second, microbes could *compete* with tumor cells and deprive them of essential nutrients. Finally, microbes could *indirectly* destroy cancer cells by activating an antitumor immune response. It is currently thought that the main mechanism by which Coley's toxins resulted in elimination of tumors was through indirect killing of tumor cells through induction of an antitumor immune response. As such, Coley's toxins are possibly the first instance of successful *cancer immunotherapy*, a field that has rapidly expanded in the past decade.

Microbes offer several potential advantages as cancer therapies when compared to traditional cancer treatments. First, microbes may be more specific for tumors rather than for normal tissue. This could be due to tropism of microbes for the tumor microenvironment. For example, anaerobic bacteria thrive in hypoxic conditions. The centers of many tumors are hypoxic, creating an immunosuppressive environment in which radiation and chemotherapeutic agents are less effective. However, this environment is ideal for *Clostridia* species (see below), which may grow within the tumors but remain unable to spread to the surrounding normal tissue. A tropism of microbes for tumors could also be related to the genetic changes associated with tumorigenesis. For example, BCG preferentially infected bladder cancer cells harboring mutations of the RAS or PI3K-PTEN pathways (Redelman-Sidi et al., 2013). Second, our immune system has evolved to recognize and deal with microbes. Microbes are, therefore, good substrates to activate an immune response. This immune response may potentially bypass the mechanisms used by tumors to escape attack by the immune system. Finally, microbes provide a plastic platform that can be manipulated to achieve desired phenotypes. Thus, microbes can be engineered to kill cancer cells more effectively, deliver cargo to the tumor environment, activate the immune system in a beneficial fashion, or have higher tumor-specificity and a reduced toxicity profile.

In the past decades, the use of microbes for the treatment of cancer has substantially expanded beyond the original Coley's toxins. Here, I will review the current state of the use of microbes as agents of cancer therapy.

Current Use of Microbial Agents as Cancer Treatment

Microbial agents used for the treatment of cancer can be divided into bacterial, viral or protozoal. A summary of the major microbial agents in current use or under investigation for the treatment of cancer is shown in Table 1.

Bacteria

Bacillus Calmette-Guerin (BCG)

BCG is an attenuated strain of *Mycobacterium bovis* that was originally developed as a vaccine against tuberculosis. The first clue suggesting that mycobacteria, such as BCG, might be valuable as treatments for cancer was provided by the biologist Raymond Pearl, who observed in an autopsy study that cancer was less common in patients who had lesions of active tuberculosis (Pearl, 1928). Subsequently, Lloyd Old, an immunologist at the Sloan Kettering Institute in New York, showed that mice infected intravenously with BCG were more resistant to the transplantation of tumors (Old et al., 1959). Following these groundbreaking studies, other investigators attempted to use BCG as therapy for various cancers, including leukemia and melanoma (Mathe et al., 1969; Morton et al., 1974). These studies were followed, in 1976, by the first report on successful use of BCG to treat patients with bladder cancer (Morales et al., 1976).

This article is a reprint of Gil Redelman-Sidi, Microbial Agents to Treat Cancer, *Reference Module in Biomedical Sciences*, Elsevier, 2019.

Fig. 1 Potential mechanisms for the efficacy of microbial agents.

Table 1 Microbial agents for the treatment of cancer

Agent	Investigative stage
Bacterial	
<i>Mycobacterium bovis</i> BCG	Approved for clinical use in patients with non-muscle-invasive bladder cancer
<i>Salmonella typhimurium</i>	Phase I clinical trials
<i>Clostridium novyi</i>	Phase I clinical trials
<i>Listeria monocytogenes</i>	Phase II clinical trials
Viral	
<i>Talimogene laherparepvec</i> (T-VEC)	Approved for clinical use in patients with nonresectable melanoma
Vaccinia virus	Phase III clinical trials
Adenovirus	Phase II clinical trials
Protozoal	
<i>Toxoplasma gondii</i>	Preclinical studies

While no longer in use for other cancers, BCG remains the standard of care for many patients with bladder cancer. These include patients with carcinoma in situ (stage Tis), high-grade papillary tumors (stage Ta), and lamina-propria-invasive tumors (stage T1) (Hall et al., 2007; Babjuk et al., 2011). These patients first undergo transurethral resection of their cancer with removal of any visible tumors. Once tumors are appropriately staged, patients go on to receive 6 weekly instillations of live BCG intravesically (into the bladder). This is followed, in some patients, by additional intravesical instillations of BCG (maintenance treatment) every several months.

When used as described above, BCG therapy decreases the risk of recurrence compared to transurethral resection of the tumor (Han and Pan, 2006; Shelley et al., 2001). It also reduces the risk of progression of the cancer to invasive disease (Sylvester et al., 2002). The clinical outcome of patients treated with BCG is generally better than that of patients treated with intravesical chemotherapy (Shang et al., 2011; Shelley et al., 2004). It is arguably the most successful microbial treatment of cancer in current clinical use.

The mechanism of action of BCG remains to be fully elucidated. Current evidence suggest that BCG success depends on attachment of live BCG to the inner lining of the bladder leading to activation of an immune response that involves neutrophils, T-lymphocytes and natural-killer cells. This immune response eventually leads to killing of the tumor cells. As such, BCG treatment of bladder cancer is considered one of the first immunotherapies of cancer (Redelman-Sidi et al., 2014).

BCG therapy can be associated with several toxicities. Most patients who receive BCG develop symptoms of bladder irritation, such as urinary frequency or burning upon urination, occasionally accompanied by fever. These symptoms usually begin within hours after instillation of BCG and resolve spontaneously within 48 h. Around 5% of patients develop more prolonged symptoms. These can include symptoms attributable to local spread of BCG causing cystitis, prostatitis, epididymitis, or due spread of BCG to other organs, causing renal abscess, pneumonitis, hepatitis or a sepsis-like syndrome. These complications usually occur within days

to weeks after BCG therapy, but can sometimes occur months or years after BCG is given. The treatment of these complications usually involves antimycobacterial antibiotics, sometimes in combination with corticosteroids (Decaestecker and Oosterlinck, 2015).

Clostridium novyi

The genus *Clostridium* comprises of anaerobic spore-forming bacteria that include nonpathogenic commensals species of the human gut as well as pathogenic, toxin-producing species, such as *Clostridium tetani*, *C. botulinum*, *C. perfringens*, and *C. difficile*. These bacteria form spores under conditions of normal oxygen tension and germinate in anaerobic conditions. As such, clostridia have a potential advantage for cancer therapy as they could germinate in the hypoxic milieu at the center of tumors but be unable disseminate to the well-oxygenated normal tissue outside of the tumor.

Several clostridial species have been tested as treatments for cancer, including *C. tetani*, *C. butyricum*, and *C. histolyticum*. These strains perform well in destroying cells within the poorly-oxygenated center of tumors, but do not effectively lead to complete regression of tumors, including their well-oxygenated areas. To address this issue, further studies have focused on combining Clostridia with chemotherapeutic agents or genetically modifying Clostridial species to improve their cytotoxic potential (Staedtke et al., 2016).

C. novyi is a soil-dwelling, toxin-producing clostridial species that is extremely sensitive to oxygen and cannot survive in oxygenated condition in its vegetative form. *C. novyi* has been associated with cases of human infection, including cases of necrotizing fasciitis or gas gangrene. In order to render *C. novyi* nonpathogenic, the phage carrying α -toxin, a major requirement for its pathogenicity, was removed. The resulting strain was named *C. novyi*-NT (Staedtke et al., 2016).

In animal tumor models, intratumoral injection of *C. novyi*-NT spores into a variety of solid tumors results in hemorrhagic necrosis with regression of tumors. Intravenous injection of *C. novyi*-NT spores results in dissemination of *C. novyi*-NT to the tumors and tumor regression in a substantial portion of treated animals. *C. novyi*-NT was relatively safe in most animals tested, through some developed abscesses and systemic signs of infection such as weight loss and lethargy (Roberts et al., 2014; Agrawal et al., 2004).

The mechanism of action of *C. novyi*-NT appears to be mostly direct cytotoxicity against cancer cells. Interestingly, in some of these animal models, *C. novyi*-NT results not only in destruction of the poorly-oxygenated center of tumors but also of the well-oxygenated regions. This mechanism appears to be immune-dependent, with animals successfully treated with *C. novyi*-NT exhibiting resistance to re-introduction of the same tumor (Agrawal et al., 2004).

Phase I studies are currently in progress to evaluate the safety of intratumoral *C. novyi*-NT injections, alone or in combination with systemic immunotherapy.

Salmonella typhimurium

Salmonella typhimurium is a motile, gram-negative facultative anaerobe that is a causative agent of gastroenteritis. Several features of *Salmonella typhimurium* make it an attractive cancer therapy agent when compared to Clostridia species. First, *Salmonella* is pliable to genetic engineering. Many anaerobic bacteria, including *Clostridium novyi*, are challenging to genetically manipulate. However, facultative anaerobes, such as *Salmonella*, can be easily transformed to express a gene of interest at the tumor site or to delete genes associated with virulence. Second, as a facultative anaerobe, *Salmonella* preferentially colonizes the hypoxic centers of solid tumors. However, it is also able to colonize oxygen-rich regions of the tumor. *Salmonella* appears to have a high specificity for tumor tissue, achieving, in animal models, far higher titers in tumors than in the liver or spleen (Ebelt and Manuel, 2017).

Due to the concern for toxicity with wild-type strains of *Salmonella typhimurium*, attenuated strains of *Salmonella* have been used in animal studies. The attenuation typically involves engineering of auxotrophic strains which are unable to grow in the absence of certain nutrients. In animal models, treatment with these attenuated *Salmonella* strains results in slowing of tumor growth and improved survival (Wang et al., 2016).

One attenuated strain of *Salmonella*, VNP20009, was tested in human patients with metastatic solid malignancies (mostly melanoma). While it was relatively well tolerated and was able to persist in some tumors, treatment with this strain did not lead to tumor regression in most cases. Current efforts are focused on engineering novel strains of *Salmonella* with improved tumor efficacy (Wang et al., 2016).

Listeria monocytogenes

Listeria monocytogenes is a saprophytic motile gram-positive rod. In humans, *Listeria* can cause gastrointestinal infections as well as meningitis and other severe infections. Like *Salmonella*, *Listeria* can be genetically manipulated relatively easily. *Listeria* strains used for cancer therapy have been attenuated to reduce their pathogenicity. For example, one of the *Listeria* strains used in cancer therapy is the Live Attenuated Double-Deleted (LADD) strain which has deletions of the virulence genes *inlB* and *actA*. As compared to wild-type *Listeria*, this strain is highly attenuated while maintaining its antitumor efficacy (Brockstedt et al., 2004).

In the host, *Listeria* is mostly found intracellularly. It can invade a variety of cells, including macrophages and epithelial cells. Once internalized, *Listeria* can escape the phagosome and then actively spread to adjacent cells (Wood and Paterson, 2014). Due to its ability to escape the phagosome, *Listeria* can deliver factors directly into the cell cytoplasm. Antigens secreted by *Listeria* in the cytoplasm are processed and presented by major histocompatibility antigen (MHC) class I and II molecules, resulting in

recognition of the antigens by CD8-positive and CD4-positive T-cells respectively, with development of a strong cellular immune response. In the setting of cancer therapy, this property of *Listeria* can be exploited by engineering strains that secrete tumor associated antigens into the cytoplasm of cells, resulting in activation of tumor immunity. *Listeria* in this context acts as a tumor vaccine vector.

Several strains of *Listeria* expressing tumor antigens have been tested in animal tumor models. These have included models of cervical cancer, prostate cancer, breast cancer, pancreatic cancer, mesothelioma, and melanoma (Wood and Paterson, 2014). Some of these strains have advanced to clinical trials, though none is currently approved for clinical use (Flickinger Jr. et al., 2018).

Other Bacteria

Other bacterial species are under investigation as potential cancer therapy agents. Examples include *Escherichia coli*, *Clostridium beijerinckii*, and *Bifidobacterium infantis*. These species are currently still in preclinical stages of investigation and a detailed description of their use is beyond the scope of this review.

Viruses

Viruses have several advantages as agents of cancer treatment. They are highly effective at infecting cells, which they access by binding to surface receptors or by fusion with the plasma membrane. The specificity of each viral species to certain receptors can be exploited to increase the selectivity of the virus to malignant cells while sparing normal ones. Once cells are infected, viral proteins can be presented on MHC molecules on the surface of the cells, leading to killing of the cell by the immune system. Additionally, viruses may directly lyse the cells. For this reason, viruses used in cancer therapy are commonly referred to as oncolytic viruses.

A major limitation of the use of oncolytic viruses is that the antiviral immune response may dampen treatment efficacy. Particularly, the antiviral immune response may preclude systemic treatment with the virus, as it may neutralize the virus before it reaches the tumors. This issue is aggravated by repeated administration of the virus, as immunity may build over time, or if there is a preexisting immunity to the viral species used. Oncolytic viruses are, therefore, typically administered via intratumoral injection. In the setting of intratumoral injection, injected tumors respond to the virus through a combination of direct lysis by the virus and immune-mediated destruction, while distant tumors which have not been injected respond through development of an antitumor immune response (abscopal effect).

Talimogene laherparepvec

Talimogene laherparepvec (T-VEC) is the only viral agent currently approved for clinical use as a cancer therapy. It is an attenuated strain of Herpes Simplex Virus (HSV) which was genetically engineered to express granulocyte macrophage-colony stimulating factor (GM-CSF) (Hu et al., 2006). GM-CSF is a white blood cell growth factor that, under physiologic conditions, stimulates stem cells to produce granulocytes and monocytes and also activates mature neutrophils and macrophages. In the context of T-VEC, GM-CSF appears to enhance oncolysis by induction of an immune response through promotion of antigen presentation by dendritic cells.

An initial phase I trial of T-VEC administered by intratumoral injection in patients with a variety of tumors, including melanoma, showed a good safety profile with evidence of antitumor efficacy in some of the patients treated (Hu et al., 2006). A subsequent phase II study in patients with nonresectable melanoma showed an overall response rate of 26%, with a 58% 1-year survival (Senzer et al., 2009). These studies led to a phase III randomized-controlled clinical trial comparing intratumoral injections of T-VEC to subcutaneous GM-CSF in patients with unresectable stage 3B, 3C or 4 melanoma. Durable disease response (disease response lasting more than 6 months) occurred in 16.3% of patients in the T-VEC arm compared to 2.1% of those in the GM-CSF arm ($P < .001$). There was a trend toward improved overall survival in the T-VEC arm compared to the GM-CSF arm 23.3 months versus 18.9 months, respectively ($P = .051$). Importantly, the antitumor effect of T-VEC was also observed in distant tumor sites that were not injected (Andtbacka et al., 2015). These trials led to approval of T-VEC for the treatment of nonresectable melanoma.

With the advent of checkpoint blockade, current efforts are focused on combining T-VEC with checkpoint inhibitors, including cytotoxic T-lymphocyte-associated antigen-4 (CTLA-4) and PD1/PDL1 antibodies. In a phase Ib trial, a combination of T-VEC with ipilimumab (CTLA-4 blocking antibody) in patients with advanced melanoma was associated with a 44% rate of durable response (lasting at least 6 months), and 50% progression-free survival and 67% overall survival at 18 months (Puzanov et al., 2016). These rates of response are higher than those seen in prior studies of either agent alone. In a phase II trial of patients with nonresectable melanoma, 39% of those receiving a combination of T-VEC with ipilimumab had an objective response as compared to 18% of those receiving ipilimumab alone ($P = .002$) (Chesney et al., 2018).

Trials are ongoing to determine the utility of combining T-VEC with checkpoint blockade. Additionally, T-VEC is being tested in other solid tumors, including pancreatic cancer, breast cancer, sarcoma, and nonmelanoma skin cancer. Beyond T-VEC, other genetically-engineered HSV strains are currently being tested in clinical trials (Fountzilas et al., 2017).

Vaccinia Virus

Vaccinia virus is a large, double-stranded DNA virus that was originally used as a vaccine against smallpox. Unlike HSV, its entire replication cycle takes place within the cytoplasm of the infected cell, and it does not enter the nucleus. Its large genome, which is approximately 192,000 base-pairs in length, allows insertion of large amounts of foreign DNA, making it an appealing option for gene delivery into tumors. It has a good safety profile and there is extensive experience using it, given that it has been used extensively in humans as a vaccine to eradicate smallpox (Haddad, 2017).

For a variety of reasons, Vaccinia virus has a tropism for tumors as compared to normal tissue (McCart et al., 2001). This is particularly true for Vaccinia virus strains that have been engineered for cancer therapy. These strains are typically deleted for the thymidine kinase (TK) gene, limiting their ability to synthesize nucleotides, and allowing them to replicate only in nucleotide rich cells, including cancer cells (Haddad, 2017).

Several Vaccinia virus strains have been tested in human cancers. JX-594, a vaccinia virus strain deleted for the TK gene and expressing GM-CSF, was tested by intratumoral injection in phase I studies in patients with melanoma and hepatocellular carcinoma (HCC). The strain had a good toxicity profile and response to treatment was seen in some of the patients treated (Park et al., 2008; Mastrangelo et al., 1999). Administration of JX-594 by the intravenous route was tested in a phase I study in patients with colorectal cancer. In this study, JX-594 was well tolerated, and 67% of the patients had radiographically stable disease (Park et al., 2015).

In a phase II clinical trial, intratumoral injections of JX-594 to patients with HCC were associated with responses of both the injected and the noninjected tumors, showing evidence of an abscopal effect of JX-594 injection. There was a dose-dependent response, with improved survival in those who received a high dose of JX-594 compared to those who received a low dose (Heo et al., 2013). There is currently an open phase III clinical trial in patients with HCC to compare JX-549 with sorafenib (angiogenesis inhibitor) to sorafenib alone.

Another Vaccinia virus strain in clinical testing is GL-ONC1, which was engineered by inserting the genes Ruc-GFP, β -glucuronidase, and β -galactosidase into Vaccinia virus. This virus was tested in two phase I clinical trials in patients with peritoneal carcinomatosis, where it was administered by intraperitoneal injection, and in patients with head and neck cancer, where it was administered intravenously. In both trials GL-ONC1 was found to be safe with some evidence of antitumor efficacy (Mell et al., 2017; Lauer et al., 2018). Phase II clinical trials of GL-ONC1 are currently underway.

Adenovirus

Adenoviruses are nonenveloped double-stranded DNA viruses. There are over 60 serotypes of adenovirus that can cause infections in humans. These strains can cause a variety of clinical manifestations, depending on the serotype involved, including respiratory, gastrointestinal, and urinary tracts and conjunctival infections. As compared to Vaccinia virus, adenoviruses have a much smaller genome, typically less than 40,000 base-pairs in length.

There are two main issues associated with adenovirus-based treatment of cancer. First, wild-type strains of adenovirus are not selective to tumors and may also infect normal tissue, particularly the liver for which they have a tropism. Second, they are highly immunogenic, potentially limiting their efficacy in vivo. To address these issues, oncolytic adenovirus strains have been modified to improve their tropism for tumors and to decrease their immunogenicity (Yamamoto et al., 2017).

Several strains of adenovirus have been tested in humans. ONYX-015 is a strain of adenovirus that can cause lysis in cells that have a mutation in the p53 oncogenes, making it selective for tumor cells carrying this mutation. This strain was tested in a phase II study via intratumoral injection in patients with head and neck cancer who received concurrent chemotherapy. There was complete response of the injected tumors in some of the patients who received intratumoral ONYX-015, but progression in all patients who received chemotherapy alone (Khuri et al., 2000). However, further studies utilizing this strain failed to replicate these results, and there are no current clinical trials involving ONYX-015.

CG0070 is an adenovirus strain expressing GM-CSF which was designed to be specific for cancer cells with alterations in the retinoblastoma pathway. In a recent phase II study, 45 patients with nonmuscle invasive bladder cancer who had failed to respond to BCG treatment or experienced recurrence after BCG were treated with CG0070. CG0070 was administered into the bladder of these patients at weekly intervals for a total of six administrations. The treatment was relatively well tolerated and 47% of the patients had a complete response after 6 months (Packiam et al., 2018).

DNX-2401 (delta-24-RGD) is another adenovirus strain that was designed to specifically infect cells with alterations in the retinoblastoma pathway. It was tested in a phase I trial in patients with recurrent brain gliomas. Patients were treated with a single intra-tumoral injection of DNX-2401. The treatment was generally well-tolerated, and 3 of 25 patients had a complete response (Lang et al., 2018).

A fourth adenovirus strain, called Enadenotucirev, was evaluated in a phase I study. In this study, Enadenotucirev was administered intravenously to patients with resectable tumors of various types. Enadenotucirev was detected in the resected tumors of most patients but was found to a much lesser degree in normal tissue. There were no adverse events related to tumor.

Other Oncolytic Viruses

Multiple other oncolytic viruses are in preclinical stages of investigation as agents of cancer therapy. These include oncolytic viruses based on Newcastle disease virus, reovirus, parvovirus, measles virus, and vesicular stomatitis virus, among others (Fountzilias et al., 2017).

Protozoa

Toxoplasma

Toxoplasma gondii is a protozoan parasite that can be transmitted via contact with cats. *Toxoplasma* infection is typically asymptomatic in immunocompetent humans; however, it can cause severe infections in immunocompromised individuals, including those with AIDS. *Toxoplasma* is an obligate intracellular organism, meaning that it can only replicate within cells.

For use in cancer therapy, *Toxoplasma* has been engineered to completely prevent its replication. This has been done by creating a strain of *Toxoplasma* that lacks the pathway for synthesis of uridine 5'-monophosphate, resulting in a mutant that can only grow if supplied with exogenous uracil, a metabolite that is not available within the host. This mutant can invade host cells but is unable to replicate. It is highly immunogenic but nonpathogenic, making it an attractive vector of cancer immunotherapy (Fox and Bzik, 2002; Fox and Bzik, 2010; Dupont et al., 2014; Fox et al., 2016).

In preclinical animal models, vaccination with this attenuated *Toxoplasma* strain results in rejection of implanted tumors. The cured mice are also resistant to re-challenge with the same tumor cell line. Tumor rejection appears to be related to activation of tumor-associated T-cells with increased production of the T-cell chemokines CXCL9 and CXCL10 within the tumors as well as increased production of interleukin-12 (Fox et al., 2016; Baird et al., 2013a). The mechanism for this may be infection of suppressive myeloid derived cells, including dendritic cells, within the tumors with reversal of their suppressive functions (Baird et al., 2013b).

There are no current clinical trials evaluating *Toxoplasma* as a cancer treatment.

Conclusions

Microbial agents have been used to treat cancer for over a century, however it is only in the past two decades that scientific understanding of microbial genetics and tumor immunology have combined to yield novel microbial strains for use in the treatment of cancer. Some microbes, such as BCG and T-VEC are already approved for clinical use. Many others are in various stages of clinical and preclinical investigation. With the recent explosion of the field of cancer immunotherapy, future studies will likely test the combination of microbial agents with checkpoint blockade and other forms of immunotherapy. It is conceivable that these combinations will be synergistic and will improve treatment outcomes. As our understanding of cancer biology and immunology keeps expanding, future investigations are expected to yield novel genetically engineered microbial strains with higher specificity for cancer cells and better efficacy in the treatment of cancer.

Biofilms in Health and Disease

Biofilms are rigorously studied because they promote bacterial pathogenesis and drive infectious diseases. Recent microbiome studies reveal the crucial role of the biofilm microbiota in modulating health and disease. Although the human microflora is established not long after birth, studies suggest that the gut microflora, in particular, can be altered not only by antibiotics, but variations in diet (Tamburini et al., 2016). Interestingly, alterations in diet can prompt the gut microbiota to undergo metabolic switches and modulate host metabolites, and as a result, byproducts of microbial and altered host metabolism can impact overall health and disease. Disruptions in the gut microbiota have been implicated in the onset of obesity, irritable bowel syndrome, colon cancer, and cardiovascular disease, among other disorders (Cho and Blaser, 2012; Gilbert et al., 2016; Lewis et al., 2015). Using 'omics techniques (genomics, metabolomics, and proteomics), microbial metabolic pathways associated with health and disease can be identified. Similarly, next-generation sequencing of 16 s rRNA bacterial signatures enables the identification of specific genera of bacteria associated with health and disease in an effort to identify microbes specifically associated with health (Cho and Blaser, 2012; Gilbert et al., 2016). A metatranscriptomics study of the oral microbiome found clear differences in metabolism between health and disease-associated microbial communities and these differences were conserved between patients (Jorth et al., 2014). Altogether, current microbiome studies highlight the role biofilm communities play not only in active infectious diseases, but also in metabolic syndromes and other systemic diseases, which further highlights the impact biofilms have on human health.

Biofilm Composition, Structure and Function

In the biofilm community, bacteria are encapsulated within a highly structured, complex matrix. Typically, the matrix is comprised of water, microbial cells, extracellular polysaccharides, proteins, extracellular DNA (eDNA), lipids and small ions (Flemming and Wingender, 2010; Payne and Boles, 2016). Together, these biofilm components support a matrix that serves as protection for the bacteria while permitting the exchange of nutrients and oxygen. Biofilm formation occurs in 4 stages: 1) attachment 2) microcolony formation 3) maturation and 4) dispersal (Fig. 1). Attachment involves an initial stage when planktonic bacteria bind to a surface in a reversible manner, followed by a stage in which planktonic that incorporated into the biofilm are no longer able to detach. Cell surface associated proteins called fimbriae and pili, and exopolysaccharides have been demonstrated to be instrumental both in vitro and in vivo for attachment of bacteria to abiotic or biotic surfaces, in addition to facilitating the incorporation of other bacteria into the biofilm (Garnett et al., 2012; Ghafoor et al., 2011; Koo et al., 2010; Liang et al., 2011; Reardon-Robinson et al., 2014). The attachment of microbes to a surface induces the expression of genes that promote the biofilm mode of growth which results in microcolony formation or microbial aggregates that are spatially arranged in an exopolysaccharide matrix (Flemming and Wingender, 2010). As the biofilm matures, various environmental cues can signal the dispersal of the biofilm, including the depletion of nutrients, toxin build-up, oxygen availability, or stress (Flemming and Wingender, 2010).

Extracellular polysaccharides are a main constituent of many biofilm matrices. For example, the oral pathogen, *Streptococcus mutans* produces glucosyltransferases, which are enzymes that use dietary sugars to catalyze the production of sticky glucans that

[☆]Change History: September 2016. Fig. 1 Stages of biofilm development in the oral cavity. Attachment of planktonic cells, activation of signaling cascades (QS and c-di-GMP) that regulate EPS production, microcolony formation, maturation, and biofilm dispersal triggered by the depletion of nutrients, environmental stress, or inhibitors that target QS or EPS.

allow the bacterium to adhere to the tooth surface (Koo et al., 2010). The opportunistic pathogen *Pseudomonas aeruginosa* produces exopolysaccharides alginate, Pel, and Psl that are differentially regulated at different phases of biofilm development and in acute versus chronic isolates (Ma et al., 2012; Schurr, 2013; Scofield and Silo-Suh, 2016). Pel has also been shown to cross-link with eDNA, which forms an unappreciated biofilm structural scaffold that may be conserved among various biofilms (Jennings et al., 2015). The production of biofilm matrix components is often controlled by coordinated community behavior known as quorum sensing or through secondary messenger activity. Quorum sensing (QS) is cell density-dependent communication between bacteria in which the production of autoinducers regulates certain community behaviors, such as exopolysaccharide production (Sakuragi and Kolter, 2007; Ueda and Wood, 2009). The requirement of QS signaling to control biofilm formation is well documented for *Vibrio cholera*, the causative agent of cholera, and *P. aeruginosa* (Kamruzzaman et al., 2010; Ueda and Wood, 2009). In addition to QS signaling, second messenger cyclic diguanylate (c-di-GMP) or cyclic diadenylate (c-di-AMP) plays crucial roles in regulating biofilm formation by many bacteria, including, *Bacillus cereus*, *P. aeruginosa*, and *S. mutans*, and *Klebsiella pneumoniae* (Fagerlund et al., 2016; Peng et al., 2016; Valentini and Filloux, 2016; Wilksch et al., 2011). Increased intracellular concentrations of c-di-GMP or c-di-AMP mediate biofilm formation via distinct signaling cascades, which can be explored to develop anti-biofilm drugs. Furthermore, QS signaling and c-di-AMP or c-di-GMP signaling may cross talk, which enrich and enhance the regulatory capacity of bacteria within biofilms.

Mechanisms of Adaptation and Persistence in Biofilms

Cells growing within biofilms often exhibit increased tolerance to antimicrobials compared to free living planktonic bacteria, and as a result, eradicating the biofilm bacteria has long been recognized as a persistent challenge in treating recalcitrant infections. In the biofilm lifestyle, bacteria have adopted several strategies that permit them to avoid clearance by antibiotics and evade the host immune response. Some of these strategies include the utilization of drug efflux pumps that prevent antibiotics from reaching high concentrations in the cytoplasm, the development of persister cells, which are dormant, drug-tolerant cells that persist subsequent to drug treatment, and the activation of stress response genes (Lewis, 2005; Liao et al., 2013; Mulcahy et al., 2010). A transcriptomic study in *P. aeruginosa* revealed that biofilms challenged with tobramycin or ciprofloxacin overexpressed genes controlled by the stress response sigma factor, RpoS, as well as genes that are devoted to hypoxia and osmotic stress (Stewart et al., 2015). Moreover, the SOS response system is required for biofilm, nutrient-deprived cells to acquire increased resistance to ofloxacin (Bernier et al., 2013). In addition, proteomic studies demonstrate that *Candida albicans* persister cells exposed to antifungal drugs upregulate proteins involved in stress response (Li et al., 2015).

Historically, exopolysaccharides have been shown to play a role in bacteria resisting antimicrobials and the immune response. For instance, *P. aeruginosa* exhibits the mucoid phenotype caused by an overproduction of exopolysaccharide alginate, which prevents the penetration of antibiotics, and inhibits phagocytosis and the activation of complement. As a result, *P. aeruginosa* is able to resist clearing by therapeutic measures and the host immune system. New evidence suggests that another major *P. aeruginosa* polysaccharide, Psl, provides the “first line of defense” against antimicrobials by promoting biofilm tolerance to cationic and anionic antibiotics (Billings et al., 2013). In addition, a different *P. aeruginosa* polysaccharide, Pel, increases resistance to aminoglycoside antibiotics (Colvin et al., 2011). Moreover, the activity of two glycosyltransferases (*epa I* and *epa OX*), which are predicted to be involved in polysaccharide biosynthesis, are critical for the biofilm formation by *Enterococcus faecalis* in the presence of antibiotics (Dale et al., 2015). Similarly, fungal β -1, 3 glucans play a role in *Candida* species’ resistance to antibiotics in single (Nett et al., 2010) and dual species biofilms with *Escherichia coli* (De Brucker et al., 2015). Taken together, current data suggest that polysaccharides not only function in maintaining biofilm structure, but serve as protection against antimicrobials.

Biofilm Microbe-Microbe Interactions and Pathogenesis

Many studies that examine factors involved in biofilm formation focus on studying single species models. However, in many cases, such as the oral cavity, chronic infections, or natural habitats, biofilms are always polymicrobial. Complex and dynamic mixed species biofilm communities can significantly alter health and disease outcomes. Emerging studies are now focusing on evaluating

the impact that polymicrobial biofilms have on the host, in addition to how diverse species of bacteria influence community behavior. In vitro and in vivo biofilm models have been developed to study biofilms containing two or more species. *P. aeruginosa* and *Burkholderia cenocepacia* are two bacteria that commonly co-infect the cystic fibrosis airway. Co-infection results in the promotion of *P. aeruginosa* biofilm and a heightened host immune response in a murine model of chronic infection (Bragonzi et al., 2012). Infection by a mixed species biofilm of *Staphylococcus aureus*, *P. aeruginosa*, *Enterococcus faecalis* and *Finnegoldia magna* severely impaired wound repair. In addition, the bacteria within the mixed species infection exhibited higher tolerance to antimicrobials (Dalton et al., 2011). These data demonstrate that bacteria in a polymicrobial biofilm may display synergism in the host, which could exacerbate microbial infection.

Oral biofilms are another example of a polymicrobial environment. Oral biofilms are comprised of mostly commensal streptococci. Commensal streptococci such as *Streptococci sanguinis*, *Streptococci gordonii*, and *Streptococcus parasanguinis*, are primary colonizers of the tooth surface. These streptococci play a role in containing the attachment of the cariogenic pathogen *S. mutans* into the oral biofilm. *S. mutans* produces a sticky glucan matrix that assists the bacterium in adhering to the tooth surface and ultimately cause tooth decay. The balance between commensal streptococci and *S. mutans* is a key indicator in predicting the health and disease outcomes, and this balance is largely driven by antagonistic interactions within the dental biofilm. Commensals in dental plaque can maintain homeostasis, however, a disruption in the oral flora could lead to dysbiosis. Several studies have elucidated the interactions of commensals and pathogens in dental plaque. Colonization sequence, hydrogen peroxide production by commensal streptococci and bacteriocin production by *S. mutans* drive bacterial competition in the dental biofilm (Fujishima et al., 2013; Kreth et al., 2008). As a result, *S. mutans* must employ several mechanisms to resist oxidative stress in the oral cavity, which includes harboring the peroxide resistance protein (Dpr), superoxide dismutase (*sod*), and *perR* (Fujishima et al., 2013; Yoshida et al., 2015), which facilitate the ability of *S. mutans* to coexist in the presence of hydrogen peroxide producing streptococci. In contrast, arginine metabolized by commensal streptococci can rebalance oral biofilms by increasing pH and shifting the microbiota towards healthy flora (Kolderman et al., 2015; Nascimento et al., 2014). Commensals themselves do not cause disease, however, they can promote the virulence of pathogens. The oral commensal, *Streptococcus gordonii*, promotes fitness and virulence of the periodontal pathogen *Aggregatibacter actinomycetemcomitans* (*Aa*) by producing the pathogen's preferred carbon source, controlling its spatial location at an infection site, and enhancing the bioavailability of oxygen to *Aa* (Ramsey et al., 2011; Stacy et al., 2014, 2016a,b). In contrast, the fitness of *Aa* is reduced when co-colonized with the oral commensal *Streptococcus parasanguinis*, and interestingly, *Aa* enhances biofilm formation by *S. parasanguinis* by modulating its hydrogen peroxide production (Duan et al., 2016). These studies suggest that specific commensals may exhibit either synergism or antagonism in the presence of pathogens. In addition to commensal-pathogenic bacterial interactions, there are examples of cross-kingdom interactions between bacteria and fungi where fungi can modulate bacterial colonization and virulence. For instance, *S. mutans* and *Candida albicans* are frequently detected together in dental plaque. Co-infection with *S. mutans* and *C. albicans* promotes biofilm formation and disease progression compared to a single infection with either species. In addition, co-infection with *C. albicans* triggers the activation of several *S. mutans* virulence genes (Falsetta et al., 2014). *C. albicans*, also co-infects the cystic fibrosis airway with *P. aeruginosa*, which can either stimulate or attenuate *P. aeruginosa* virulence and biofilm formation using various mechanisms (Chen et al., 2014; Lopez-Medina et al., 2015). *C. albicans* can also influence other fungal species by enhancing the expression of *Candida glabrata* cell wall adhesins and the colonization of *C. glabrata* on tongue tissue (Tati et al., 2016). Owing to the fact that multiple species of microbes are found at infection sites and engage in interactions that affect microbial fitness and virulence, it is critical to elucidate mechanisms of microbial synergism and antagonism in polymicrobial biofilms.

Biofilm Experimental Techniques and Emerging Biofilm Control Strategies and Therapeutics

Technological advances have facilitated the biofilm research. Use of the microtiter dish and crystal violet assay has long been a powerful tool to assess biofilm biomass (O'Toole, 2011). In addition, immunofluorescence and confocal microscopy has afforded high resolution imaging of single and mixed species biofilms. These imaging techniques permit the labeling of viable and dead bacteria in the biofilm, the visualization of matrix components such as glucan, 3D imaging of biofilms, and specific labeling of bacteria in mixed species biofilms using cell surface specific antigens. Moreover, solid-state nuclear magnetic resonance (NMR) has been used as an effective way to study cell surface associated proteins involved in *S. mutans* adhesion and the extracellular matrix of *Aspergillus fumigatus* (Reichhardt et al., 2015 and Tang et al., 2016). New tools to study biofilms will assist the research field to identify and develop new anti-biofilm targets. More recently, super-resolution light microscopy has provided the unprecedented resolution to visualize the spatial organization of the extracellular matrix proteins (Berk et al., 2012). Understanding the spatial arrangement of microbes in a biofilm is important largely because the biogeography of microbes in polymicrobial infections is linked to virulence potential (Stacy et al., 2016a,b). In vivo fluorescent probes coupled with metagenomic sequencing allows the monitoring of the biogeographical distribution of bacteria on a micron scale (Mark Welch et al., 2016). Other tools combine segmentation and image analysis algorithms with a spinning-disk confocal microscope to image the evolving 3D architecture of *V. cholera* biofilms, which allows researchers to examine biofilms at single-cell resolution (Drescher et al., 2016). In addition, micro-3D printing and scanning electrochemical microscopy (SECM) can image bacterial aggregates in situ to examine QS signaling, behavior, and spatial organization within the biofilm (Connell et al., 2014). Collectively, these new technologies will drive the development of therapeutics that disrupt the biogeographical arrangement of polymicrobial biofilms.

In the post-antibiotic era much emphasis has been focused on developing novel non-antibiotic therapeutics to target biofilms. Due to the high level of drug resistance exhibited by recalcitrant pathogens, such as methicillin-resistant *Staphylococcus aureus*,

P. aeruginosa, *Acinetobacter baumannii*, in addition to robust biofilms produced by *S. mutans*, the efforts in developing anti-biofilm strategies have shifted towards more targeted approaches. Specific genes or pathways that play a direct role in biofilm formation are now being directly targeted in an effort to block the synthesis or activity of biofilm related constituents. Due to the fact that QS genes directly regulate biofilm formation in various bacteria, inhibitors of QS are now being considered as potential biofilm targets. Drug targets of the *las* and *rhl* QS systems of *P. aeruginosa* have been developed that target or degrade the acyl-homoserine lactones (AHLs) structure. These inhibitors have been shown to not only attenuate biofilm formation, but downregulate cytotoxic virulence factors in *P. aeruginosa* (Furiga et al., 2016; O'Loughlin et al., 2013) and *S. aureus* (Srivastava et al., 2015). Other techniques involved the use of small molecules that target DnaK in *E. coli*, cell wall biosynthesis in *Mycobacterium tuberculosis*, and dihydrofolate reductase in *S. mutans*, are also promising as they also inhibit biofilm formation in the respective bacteria (Arita-Morioka et al., 2015; Wang et al., 2013; Zhang et al., 2015). Targeting microbial geography by disrupting the exopolysaccharide matrix is another mean to disrupting biofilms. For example, PslG, a protein involved in the biosynthesis of the major *P. aeruginosa* biofilm polysaccharide, Psl, disrupts the Psl matrix and disassembles pre-existing biofilms when added exogenously (Yu et al., 2015). Moreover, nanoparticles that exploit the acidic pH of the oral biofilm can deliver farnesol to interfere with exopolysaccharides in the biofilm matrix (Horev et al., 2015). Similarly, nanocatalysts have been shown to degrade *S. mutans*' matrix and increase bacterial killing (Lizeng et al., 2016). Overall, the approach of using specific targets that inhibit QS signaling or biofilm matrix components appears to be a viable strategy for inhibiting biofilms.

Conclusion

Biofilm formation contributes to the microbial persistence and virulence. We are frequently uncovering new mechanisms utilized by microbes to form biofilms. More importantly, scientists are beginning to appreciate the significance of polymicrobial biofilms, since infections often involve multiple species of microbes and these microbes engage in complex and dynamic interactions that impact the outcomes of health and disease. Fortunately, the rapid development of new, powerful technologies and tools will provide the needed resolution to study intricate details of microbial biofilms, which will ultimately result in the development of novel and advanced anti-biofilm therapeutics.

Introduction

Methane, produced both abiogenically, through processes in the Earth's crust (Sherwood Lollar et al., 2002, 2006; Etiope and Sherwood Lollar, 2013) and biogenically, through microbial methanogenesis (Singh et al., 2010), is an important component of the global carbon cycle. Microbes that consume methane, the methanotrophs, play a major role in methane emission mitigation (Conrad, 2009). Methane-metabolizing species have been recognized within the bacterial and archaeal domains of life, and it has been recognized that methane metabolism can proceed either aerobically or anaerobically (Chistoserdova and Lidstrom, 2013; Chistoserdova, 2015). This article aims to summarize the diversity and environmental distribution of methanotrophs and recent developments in the understanding of the metabolic details specific to each subgroup. We also touch on recent developments in the potential role of lanthanides as environmental regulators of methane metabolism, as well as on the increasingly recognized concept of syntrophies as parts of microbial methane metabolism.

The Methane Cycle

While methane is produced in essentially every ecosystem, from the deep ocean to the human gut, the scale of the global methane cycle, in the context of the global carbon cycle, is sometimes difficult to fully appreciate. This is partly due to the complexity and the variety of its sources and sinks, which we briefly summarize below. An annual input of methane carbon into the Earth's atmosphere, in the form of emitted methane, is calculated at 325–500 Tg ($\text{Tg}=10^{12}$ g C) (Shindell et al., 2012; Tian et al., 2016). Approximately 70%–80% of the newly added methane is oxidized photo-chemically in the troposphere and the stratosphere, ~5%–10% contribute to the atmospheric methane pool, and ~20% are consumed via biological activities in terrestrial ecosystems (woodland soils, deserts, etc.) (Striegl et al., 1992; Bender and Conrad, 1995; Topp and Pattey, 1997; Shrestha et al., 2012). However, it is important to remember that the emitted methane is only a small portion of the annual biological methane cycle (Fig. 1). The global methane pool is built upon numerous atmospheric, biomass-based, fossil, and geothermal reservoirs. The abundance of methane in the Earth's atmosphere is slowly approaching 5 Gt of carbon (1 Gt=1000 Tg), making it the most abundant organic compound. As one of the main end products of biomass decomposition occurring in anaerobic (via methanogenesis) and aerobic (via methylphosphate degradation) conditions, methane is produced in every ecosystem where biomass decomposition occurs. The deposits of thermogenic, primary and secondary methane gas, and geological (abiotic) methane are estimated at 2500 Gt of carbon (Milkov, 2011; Etiope and Sherwood Lollar, 2013). Every year, a portion of fossil methane leaks to overlying areas, stimulating chemosynthesis and providing additional sources to ecosystems (Chapelle et al., 2002; Thauer et al., 2008; Orcutt et al., 2013; Kietäväinen and Purkamo, 2015; Chronopoulou et al., 2017). Methanotrophs play a major role in methane consumption, thriving across environmental niches in which its production occurs: soils (Hanson and Hanson, 1996), marine and freshwater sediments (Tavormina et al., 2010; Trimmer et al., 2015), tissues of mollusks (Fiala-Médioni et al., 2002) and even human gut (Clemente et al., 2015).

Diversity of Methanotrophs

Beyond the use of methane as a carbon and energy source, methanotrophs have both numerous cellular features in common and significant metabolic differences between the functional types. The two main groups of methane-utilizing prokaryotes are the methanotrophic archaea (ANME) and the methanotrophic bacteria, the former typically associated with anaerobic metabolism of methane, while the latter can metabolize methane both aerobically and anaerobically (Figs. 2 and 3).

Methanotrophic Archaea

Geochemical evidence suggesting microbial anaerobic oxidation of methane linked to sulfate reduction has existed since the late 1970s (Reeburgh, 1976, 1980). However, it took another two decades to obtain molecular evidence that the microbes involved are Euryarchaeota archaea (ANME), a phyla closely related to *bona fide* methanogens and their syntrophic partners, sulfate-reducing bacteria (SRB) (Hinrichs et al., 1999; Boetius et al., 2000; Orphan et al., 2001; Knittel and Boetius, 2009). The biochemical pathways potentially involved in such cooperative metabolisms were teased out via metagenomics studies, as none of the partner organisms were available in culture. Sequence analysis strongly suggested that a reverse methanogenesis pathway must be involved in methane oxidation (Hallam et al., 2004; Fig. 3(B)). This hypothesis was further supported by high expression of methanogenesis genes in

Fig. 1 (A). Overview of the global methane cycle. It could be estimated that methane-utilizing microbes are responsible for consumption of 2–2.5 Gt of methane carbon each year. Overall, methanotrophy plays an important role in local carbon turn-over in a variety of terrestrial ecosystems.

Fig. 2 Schematic illustration of metabolic coupling in methane oxidation. (A–E) Oxygen-dependent methane oxidation, which is now known to occur in aerobic, microaerobic, and anaerobic environments. Methanotrophic bacteria employ various strategies to cope with low oxygen tensions, including switch to fermentative lifestyle (B), denitrification (C–D), or close cooperation of oxygen-producing cyanobacteria (E); (F–G) Oxygen-independent methane oxidation is driven by anaerobic archaea that are capable of denitrification or metal reduction (F) and sulfate reduction (G). PB, proteobacteria; V, Verrucomicrobia; NC, NC10 bacteria; AR, archaea; SRB, sulfate-reducing bacteria; NBR, denitrifying bacteria; CB, cyanobacteria; OC, organic carbon; OA, organic acids.

Fig. 3 Schematic illustration of methane oxidation. (A) aerobic and (B) anaerobic methane oxidation. pMMO, membrane-bound methane monooxygenase; sMMO, soluble methane monooxygenase; MDH (Mxa or Xox), PQQ-linked methanol dehydrogenases; H₄MPT, tetrahydromethanopterin-linked C1 transfer; H₄F, tetrahydrofolate-linked C1 transfer; FaDH, formaldehyde dehydrogenase; FDH, formate dehydrogenases; NDH, NADH:quinone oxidoreductase; d-RuMP, dissimilatory ribulose monophosphate cycle; f-RuMP, RuMP-phosphoketolase pathway for fermentation of methane; MCR, methyl-coenzyme M reductase; MTR, Methyl-H₄MPT:coenzyme M (CoM) methyl-transferase; HDR/MVH, coenzyme M-coenzyme B (CoM-S-S-CoB) heterodisulfide reductase and D subunit of F₄₂₀-nonreducing hydrogenase; FMD, Formyl-MFR dehydrogenase; MER, Methylene-H₄MPT dehydrogenase; Cyt, cytochrome; AcK, acetate kinase; NAR, nitrate reductase; NRF or NIR, nitrite reductases; NOR, nitrous oxide reductase.

ANME-dominated cultures (Meyerdierks et al., 2010; Stokke et al., 2012; Wang et al., 2014). The metagenomic data were also in agreement with data showing highly abundant proteins in ANME-dominated microbial mats, identified as subunits of methyl-CoM reductase (MCR) (Krüger et al., 2003). These metagenomic studies, lending strong support for reverse methanogenesis, have facilitated further progress in understanding the process of ANME, including mechanisms for methane activation and interspecies electron transfer. Validation of the involvement of MCR in methane activation has been demonstrated experimentally by showing reverse reaction activity for an MCR from a bona fide methanogen (Scheller et al., 2010). Additional validation was obtained through purification and crystallization of an MCR homolog from an ANME-enriched microbial mat (Shima et al., 2011). This enzyme revealed striking structural similarities with MCR enzymes involved in methanogenesis (Shima et al., 2011), further suggesting that methane production and methane oxidation may rely on the same enzyme acting in reverse. Indeed, it has been demonstrated that ANME organisms can both produce and oxidize methane, a conclusion based on quantification of gene transcripts in zones of methane oxidation and methane production separated across the depths of a sediment (Lloyd et al., 2011). Direct coupling of methane oxidation to sulfate reduction by ANME organisms without the requirement of SRB partners (Milucka et al., 2012) was proposed to resolve potential mechanisms for interspecies electron transfer. However, this proposal contradicted the well-documented co-occurrence and tight physical association of ANME and SRB (Boetius et al., 2000; Orphan et al., 2001). An alternative hypothesis of direct electron transfer (DIET) between ANME and SRB has been supported by data from several recent studies (McGlynn et al., 2015; Wegener et al., 2015; Krukenberg et al., 2016). Further support for DIET was obtained through decoupling methane oxidation from sulfate reduction using artificial electron acceptors (Scheller et al., 2016). Respiration

with solid electron acceptors via extracellular metal reduction could be one mechanism responsible for the described processes coupled to insoluble iron (III) and manganese (IV) (Beal et al., 2009).

Methane oxidation by ANME can also be linked to denitrification (Haroon et al., 2013; Arshad et al., 2015). This metabolism was proposed to involve a different syntrophic partner, the anaerobic ammonia-oxidizing bacteria of the genus *Kuenenia* (Planctomycetes) (Haroon et al., 2013). Recently, novel lineages of archaea were identified, including Thorarchaeota (Seitz et al., 2016), Bathyarchaeota and MSBL1 (Evans et al., 2015; Mwirichia et al., 2016; Lazar et al., 2016), for which a role in methane metabolism was predicted. However, whether these novel organisms are active in methane oxidation or in methanogenesis remains to be demonstrated.

For carbon assimilation, ANME, like the methanogens, utilize the Wood–Ljungdahl pathway (Hallam et al., 2004), the -omics based evidence being supported by *in-silico* metabolic simulations (Nazem-Bokaei et al., 2016).

Methanotrophic Bacteria

Methanotrophic bacteria are found among three phyla: Proteobacteria (Alpha- and Gamma-), Verrucomicrobia, and NC10 phylum (“*Candidatus Methyloirabilis oxyfera*”) (Chistoserdova and Lidstrom, 2013). Methanotrophs are diverse in terms of cell shape: in addition to the common rod or coccoid shapes (Trotsenko and Murrell, 2008; Islam et al., 2008), spiral (Danilova et al., 2016), filamentous (Stoecker et al., 2006) and polygonal shapes (Wu et al., 2012; Gambelli et al., 2018) have been described. Frequently, the cells are decorated with surface layer (S-layer) proteins displaying hexagonal symmetry (Khmelena et al., 2010; Shchukin et al., 2011). The function of these S-layers remains unknown. One unifying feature among proteobacterial methanotrophs is the presence of networks of intracytoplasmic membranes (ICMs) that fill the cells (Weaver and Dugan, 1975; Hyder et al., 1979). Similar structures have also been detected in some verrucomicrobial methanotrophs (van Teeseling et al., 2014). However, so far, they have not been observed in “*Methyloirabilis oxyfera*”. Where present, the ICMs are assumed to house particulate methane monooxygenase (pMMO), the key enzyme involved in methane oxidation (Sirajuddin and Rosenzweig, 2015). Some methanotrophs encode a soluble type of methane monooxygenase (sMMO) (Sirajuddin and Rosenzweig, 2015). The mechanism for ICM formation remains unknown, but their presence has been correlated with the expression of pMMO that, in turn, depends on the presence of copper (Brantner et al., 1997; Murrell et al., 2000). Substrate availability also seems to be a factor in ICM formation, as starvation has been demonstrated to cause a higher content of ICMs per cell (Tavormina et al., 2017).

Methanotrophs are frequently observed to contain cytoplasmic inclusion bodies, which vary in composition between species, but which are typically formed of polymeric storage compounds. Polyhydroxyalkanoates (PHA) and glycogen are among such storage compounds (Dunfield et al., 2003; Khadem et al., 2012a), while other electron-dense inclusions have been identified as phosphate storage granules (van Teeseling et al., 2014).

As pMMO-encoding methanotrophs have high demand for copper, an essential cofactor of pMMO methane catalysis (Sirajuddin and Rosenzweig, 2015; DiSpirito et al., 2016; Semrau et al., 2018), some methanotroph species have been shown to secrete a chalkophore, methanobactin, which binds copper ions, which are then transported into cells in a form of the methanobactin-copper complex (Dassama et al., 2016; DiSpirito et al., 2016; Semrau et al., 2018).

The product of methane oxidation is methanol, which is further oxidized to formaldehyde (Anthony, 1982). One enzyme that carries out this function, a periplasmic pyrroloquinoline quinone (PQQ)-dependent, calcium-containing methanol dehydrogenase (MDH), has been identified over a half century ago and studied in detail for years (Anthony and Zatman, 1964, 1965, 1967a,b; Anthony, 2004). The enzyme consists of two subunits, large and small, MxaF and MxaI, and it is functionally linked to a dedicated cytochrome, MxaG (Williams et al., 2006). Rather surprisingly, a novel MDH has been recognized just recently, whose single type of subunit, XoxF, is homologous to MxaF. This enzyme requires lanthanides – rare Earth elements (REEs) – in its active site, instead of calcium (Pol et al., 2014; Keltjens et al., 2014). This discovery was remarkable not only in terms of demonstrating the existence of an enzyme overlooked for over a century of methylotrophy research, but also in terms of overturning the long-standing dogma of the biological inertia of REEs (Lim and Franklin, 2004). Genetic investigations in model organisms indicated that not only are REEs important for the activity of XoxF enzymes, but that they are also involved in the regulation of the alternative MDH enzymes, by decreasing expression of the *mxg* gene cluster and by increasing expression of *xox* genes (Vu et al., 2016; Chu and Lidstrom, 2016; Chu et al., 2016; Gu et al., 2016). High expression of *xoxF* genes and proteins in diverse environments, determined through metatranscriptomics and metaproteomics (Delmotte et al., 2009; Sowell et al., 2011; Mattes et al., 2013; Moitinho-Silva et al., 2014; Grob et al., 2015; Ramachandran and Walsh, 2015), also suggests that *xoxF*-encoding microbes must possess molecular mechanisms for solubilizing, chelating, and transporting REEs into cells; however, these mechanisms have yet to be discovered (Chistoserdova, 2016).

Methanotrophic bacteria can use various pathways for formaldehyde oxidation, including direct oxidation via a formaldehyde dehydrogenase (Hou et al., 2008; Khadem et al., 2012b), cofactor-mediated C1-transfer pathways, and, in organisms operating the ribulose monophosphate (RuMP) cycle, the oxidative pentose phosphate pathway (Trotsenko and Murrell, 2008). In cases when formate is the final product of formaldehyde oxidation, formate dehydrogenases (FDH) complete the primary pathways. Several types of the FDHs have been described; however, two of them, including tungsten- and molybdenum-dependent enzymes are the most prevalent (Chistoserdova, 2011).

Three different metabolic pathways can contribute to C1-carbon assimilation, including the RuMP pathway, the serine cycle, and the Calvin–Benson–Bassham (CBB) cycle (Anthony, 1982, Fig. 4). The pathways have recently undergone a revision, through matching the modern -omics data to the established knowledge in combination with enzyme and metabolite characterizations.

Fig. 4 Main pathways for carbon assimilation by methanotrophs. RuMP, assimilatory ribulose monophosphate pathway (unique enzymes 1–2); SC, serine cycle (unique enzymes/steps 3–9); CBB, Calvin cycle (unique enzymes 10–11); WLP, the reductive acetyl-CoA (Wood–Ljungdahl) pathway (unique enzymes/steps 12–14). 1. hexulosephosphate synthase; 2. hexulosephosphate isomerase; 3. H_4F , tetrahydrofolate-linked C1 transfer; 4. serine hydromethyltransferase; 5–7. serine glyoxylate aminotransferase, hydroxypyruvate reductase, and glyceralate 2-kinase; 8. malate thiokinase; 9. malyl CoA lyase; 10. phosphoribulokinase; 11. ribulose-1,5-bisphosphate carboxylase; 12. H_4MPT , tetrahydromethanopterin-linked C1 transfer; 13. carbon monoxide dehydrogenase; 14. CO-methylating acetyl-CoA synthase. Additional pathways: PPP, pentose phosphate pathway; GNG/GP, gluconeogenesis; GP, glycolytic pathway; the Embden–Meyerhof–Parnas (EMP) pathway and/or the Entner–Doudoroff (ED) pathway; EMC, ethylmalonyl-CoA pathway; GS, glyoxylate shunt.

The pathway for glyoxylate regeneration by serine cycle methylotrophs not possessing the glyoxylate shunt (GS, among them the alphaproteobacterial methanotrophs) that had remained a mystery for half a century (Anthony, 2011) has been only recently determined to be the ethylmalonyl-CoA cycle (EMC, Erb et al., 2007). The discovery of this new pathway also prompted a reevaluation of the amount of carbon assimilated in the form of CO_2 through the multiple carboxylation reactions that are key to this metabolism (Erb et al., 2007; Yang et al., 2013). Interestingly, genomic evidence indicated that the gammaproteobacterial methanotrophs also encode enzymes for all key steps of the serine cycle but not the EMC or GS (Kalyuzhnaya et al., 2015a,b). Yet the enzymes are expressed and are functional (But et al., 2017). The role of this variant of the serine cycle in these methanotrophs and its significance for methylotrophy metabolism remains to be determined. Once assumed unlikely due to low efficiency (Chistoserdova et al., 2009), assimilation of carbon from methane through the CBB cycle has been demonstrated in certain methanotrophs, such as Verrucomicrobia and NC10 Phylum (Khadem et al., 2011; Rasigraf et al., 2014).

The dogma of the ‘obligate’ dependence of methanotrophs on single carbon compounds (methane or methanol) has also been recently overturned by the demonstration of growth on and metabolism of other organic compounds such as acetate and propane, at least in alphaproteobacterial methanotrophs (Crombie and Murrell, 2014; Dunfield and Dedysh, 2014). Analysis of the genomes of multiple methanotrophs indicated the presence of all of the genes for a complete tricarboxylic acid (TCA) cycle (Kalyuzhnaya et al., 2015a; Flynn et al., 2016), contrary to prior beliefs based on enzyme activity measurements (Anthony, 1982; Trotsenko and Murrell, 2008). ^{13}C -tracer metabolomics applied to gammaproteobacterial methanotrophs in combination with mutant analysis demonstrated that a significant flux of carbon occurs through the TCA cycle, identifying this pathway as a source of not only precursors for biomass synthesis but also of reducing power (Fu et al., 2017). The TCA cycle in gammaproteobacterial methanotrophs appears to be highly branched and mostly dedicated to the production of two key amino acids, aspartate and glutamate. However, glutamate could be returned into the TCA cycle by the way of succinate-semialdehyde dehydrogenase and glutamate carboxylase, while aspartate could be converted into fumarate via aminotransferase and aspartate lyase. Thus, the function of the TCA cycle may to provide a balance between anabolic reactions and to supply the metabolites necessary for fulfilling redox demands (Akberdin et al., 2018).

Finally, the RuMP pathway now appears as a very modular route of formaldehyde assimilation. The reactions downstream from the two key steps of formaldehyde incorporation into phosphosugars might include Embden–Meyerhof–Parnas (EMP pathway) reactions, Entner–Doudoroff pathway reactions, and the *Bifidobacterium* shunt (Akberdin et al., 2018). All three pathways are interconnected with the pentose phosphate pathway reactions for the regeneration of ribulose 5-phosphate. This metabolic flexibility supports a number of additional functional abilities of methanotrophic bacteria, including conversion of C_2 -units from acetyl-CoA back into C_5 and C_6 -sugars via a reverse phosphoketolase (Akberdin et al., 2018) and the proposed acetate fermentation pathway upon growth at low oxygen tensions (Fig. 2; Kalyuzhnaya et al., 2015b).

Oxygen-Dependent Metabolism of Methane in Anoxic and Hypoxic Environments

A novel mode of metabolism has been proposed for bacteria belonging to the Candidate Phylum NC10 (tentatively named *Methyloirabilis oxifera*), which oxidize methane in anoxic or hypoxic environments, but employ the classic methane oxidation

pathway (pMMO, MDH and H₄MPT-linked formaldehyde oxidation) and the CBB assimilatory cycle (Rasigraf et al., 2014). However, no external source of oxygen was considered for their metabolism, thus oxygen was proposed to be generated intracellularly, via a modified denitrification pathway (Raghoebarsing et al., 2006; Ettwig et al., 2010). So far, this metabolic mode remains unconfirmed in terms of enzyme identities or activities. Meanwhile, the more traditional methanotrophs have also been shown to express the denitrification pathway under hypoxia, suggesting that electron acceptors alternative to oxygen may indeed be involved in methanotrophy (Kits et al., 2015; Kalyuzhnaya et al., 2015a; Fig. 2). NC10-type bacteria, both terrestrial and marine, are typically detected in environmental niches characterized by high concentrations of methane and nitrate (Zhu et al., 2012; Deutzmann et al., 2014; Padilla et al., 2016). However, multiple environmental studies provide strong evidence for the activity of true 'aerobic' methanotrophs in hypoxic and anoxic conditions. *Methylobacter* species have been identified as the most active types in arctic soils and lakes (Yergeau et al., 2010; Martineau et al., 2010; Graef et al., 2011; Tveit et al., 2013, 2014; Crevecoeur et al., 2015) while the identity of gammaproteobacterial methanotrophs in non-arctic lakes remains uncertain (Oswald et al., 2016a). In some lakes, alphaproteobacterial methanotrophs have also been detected in both oxic and anoxic layers (Oswald et al., 2016b).

Compelling evidence has been presented for anaerobic methane oxidation by Proteobacteria in the absence of nitrate (Blees et al., 2014), and none of the other alternative electron acceptors were unequivocally proven to be involved, while stimulation of methane oxidation by Fe(III) and Mn(IV) has been observed in some samples (Oswald et al., 2016b). The exact mechanism that allows 'aerobic' methanotrophs to thrive in anoxic environments remains to be discovered. A recent study that characterized a novel microaerophilic methanotroph suggested that motility may play a key role in benefiting from the optimal methane/oxygen concentrations in natural environments (Danilova et al., 2016).

One mechanism for adaptation to anoxic conditions emerged from starvation experiments, in which methanotrophs were demonstrated to survive better in the absence oxygen. Fermentation metabolism was proposed to be responsible (Roslev and King, 1994, 1995). Indeed, such a pathway has been recently demonstrated in a gammaproteobacterial methanotroph (Kalyuzhnaya et al., 2013). The ability of 'aerobic' methanotrophs to ferment has implications beyond the occurrence and distribution of aerobic methane utilization, as it also suggests a potentially much larger contribution to local and global carbon cycling than previously thought. It is likely that methane oxidation by 'aerobic' methanotrophs is the main mode of methane metabolism in ecosystems with limited but constant input of oxygen (such as shallow anaerobic freshwater sediments, anaerobic soils surrounding plant roots, or deep sea). While in some of those niches the oxygen may be present under detectable levels, a low but constant flux of oxygen from photosynthesis (Miluka et al., 2015; Oswald et al., 2015; Hill et al., 2017) or radiolysis (Lin et al., 2005) may be supporting active methanotrophic communities. However, the scale and the distribution of fermentation-based methanotrophy need further investigation.

Syntrophy and Predation in Methanotrophy

As mentioned above, anaerobic methane oxidation by either ANME or NC10 bacteria appears to depend on syntrophic associations, as, so far, none of these organisms have been isolated in pure culture. In the case of ANME, the requirement for syntrophy is assumed to be due to energetic constraints of methanotrophy via reverse methanogenesis when coupled to sulfate reduction (Thauer and Shima, 2008) or the necessity for nitrite removal when coupled to denitrification (Haroon et al., 2013). The reasons for potential syntrophic dependencies of NC10 bacteria are unknown, and it is possible that they could be obtained in pure culture based on the notion that their metabolism follows the same scheme as the metabolism of proteobacterial methanotrophs. As to the latter, while proteobacterial methanotrophs have been isolated and maintained in pure cultures for over a hundred years (Kaserer, 1906; Söhngen, 1906), it appears that in nature they also tend to form consortia, and, while carbon from methane is a hard-earned currency, they share it generously with other bacteria (Kalyuzhnaya et al., 2008; Beck et al., 2013; Oshkin et al., 2015; Hernandez et al., 2015; Yu et al., 2017; Yu and Chistoserdova, 2016, 2017). Some of the most commonly co-occurring species are non-methane-utilizing methylotrophs (Oshkin et al., 2015; Hernandez et al., 2015), which are proposed to feed on methanol leaked by the methanotrophs (Krause et al., 2017). Other co-occurring species include non-methylotrophic bacteria, most frequently members of Burkholderiales and Flavobacteriales (Oshkin et al., 2015; Hernandez et al., 2015; Yu et al., 2017), and these are likely feeding, respectively, on organic acids released by the methanotrophs (Kalyuzhnaya et al., 2013) and on the polymeric substances that are excreted by the methanotrophs and other community members (Yu et al., 2017; Yu and Chistoserdova, 2017). Little is known about what methanotrophs get in return. Among the most interesting observations is the oxygen – CO₂ exchange between methanotrophs and cyanobacteria (Miluka et al., 2015; Oswald et al., 2015; Hill et al., 2017).

Like many other bacteria, methanotrophs can be infected by viruses that may be species- to strain-specific (Tyutikov et al., 1983; Gambelli et al., 2016). Thus, virus predation is yet one additional mechanism controlling trajectories on methanotroph consortia in nature. Metabolic reprogramming of methanotroph genomes may also be mediated by viruses, based on the presence of prophages in their genomes (Kalyuzhnaya et al., 2015a; Flynn et al., 2016).

Conclusions and Future Perspectives

While the methanotrophy field is over a hundred years old, recent developments indicate that we are quite far from understanding the process precisely, and many challenging questions remain. Several long-held dogmas in methanotrophy have been overturned recently. The 'strictly' aerobic nature of the proteobacterial methanotrophs has been questioned, as well as the relevance of

laboratory performance to performance in natural environmental niches. Novel biochemistries have been recently (re)discovered, such as the XoxF-type MDH distributed across bacterial methanotrophs, the complete tricarboxylic acid cycle, and functional serine cycle in gammaproteobacteria and the EMC pathway in alphaproteobacterial methanotrophs. Gammaproteobacterial methanotrophs have been shown to be capable of fermentation. Can alphaproteobacterial methanotrophs ferment as well? Is methanotrophy different in 'anaerobic' NC10 and 'aerobic' proteobacterial methanotrophs? Is denitrification different among these species? Why do methanotrophs share their carbon with other bacteria and do they get anything in return? Are the communities formed randomly or as guild-specific or even species-specific syntrophies? We are in a good position to address these questions as we now have access to extensive genomic databases, -omics, and modeling tools. However, these challenging problems can only be solved by combining the information tools with experimental validation, for which we need appropriate model organisms. Some of the newly-emerged questions, such the role of community function in methane oxidation may require complex model communities rather than pure cultures. We look forward to the next hundred years of methanotrophy research.

VFA	Volatile fatty acids

Introduction

The rumen is the first of four pre-intestinal digestive chambers of mammals within the order Artiodactyla. The rumen is located just upstream of a second chamber, the reticulum, with which it can exchange material and which has many of the similar functions (and thus is sometimes considered together as the 'reticulorumen'). The basic functions of the rumen are to facilitate the microbial fermentation of feedstuffs to produce usable energy sources for the host (primarily volatile fatty acids, 'VFA') and microbial protein for subsequent digestion or absorption. Central to the functioning of the rumen is the process of rumination, by which partially digested feeds are regurgitated to the buccal cavity for re-chewing (the so-called 'chewing of the cud') and then re-swallowing. The mechanical movements of the buccal cavity and the structure of the animal's dentition combine to delaminate the layers of forage leaves and stems in a manner that exposes additional degradable surface while at the same time retaining the relatively long feed particle sizes that stimulates further rumination and chewing. The net effect of rumination is to decrease the size and increase the surface area of feed materials to improve their degradability, and to stimulate production of saliva that serves as the major component of ruminal fluid.

The Rumen as a Microbial Habitat

Just as ruminant species span a size range from ~3 kg to ~1200 kg, the rumen also varies in size, but typically comprises one-fifth to one-tenth of the weight of the adult ruminant host. The contents of the rumen are stratified, with a mat of freshly ingested and partially digested feeds floating atop a sea of ruminal fluid that contains feed and forage particles of various sizes and densities. The concentration of solids averages ~12%–15%, and increases gradually with depth, although periodic muscular contractions associated with rumination and animal movement keep the contents moderately well-mixed. The mat layer, primarily fibrous digesta, serves as a partial refugia for motile ruminal protists, allowing them to be selectively retained in the rumen to a degree greater than if they were freely suspended in (and washed out with) the ruminal liquid. The ruminal liquid phase has an approximate retention time of 8–12 h, while the larger solids may have retention times exceeding 48 h. It is this long retention of solids that permits the high degree of fiber fermentation that is achieved in the ruminant animal.

The ruminal fluid has a high salts content (220–420 mOsmoles L⁻¹), and is highly reducing (reduction potential –170 to –220 mV), thus supporting the growth of strictly anaerobic microbes. pH is typically maintained in the range of 6–7, but is often lower in animals consuming diets high in rapidly fermented starches or sugars. High concentrations of bicarbonate contained within saliva (produced at up to 100 L d⁻¹) and substantial concentrations of VFA (60–180 mM) work together to provide effective pH buffering.

Ruminal Fermentation Pathways

Like all fermentations, that of the rumen involves the conversion of organic materials of intermediate oxidation state to a mixture of products of higher, lower, or similar oxidation state. Most of the fermentable substrates in feeds are carbohydrates, and their fermentation products include CO₂, formate, and succinate (more oxidized); acetate and lactate (redox-neutral); and C₃–C₆ VFA and methane (more reduced). The relative proportions of these products vary depending on the specific substrate and the species composition of the microbial community. In all cases, the organisms must maintain a redox balance, which is accomplished by directing the flux of fermentation intermediates through different catabolic pathways.

The ruminal fermentation has some similarities to another economically important mixed culture fermentation, the anaerobic digestion (AD) of organic wastes. In AD, long retention times (2–4 weeks) are employed to allow a nearly complete mineralization of organic material to methane and CO₂. VFA, the conventional intermediates of AD, are fermented to acetate and H₂ (a process known as proton-reducing acetogenesis), and methane is produced both by reduction of CO₂ with H₂ (hydrogenotrophic

methanogenesis), and by cleavage of acetate to methane and CO₂ (aceticlastic methanogenesis). In the rumen, retention times are much shorter than in AD – too rapid to allow establishment of the slow-growing VFA fermenters and aceticlastic methanogens. As a result, methane yields in the ruminal fermentation are much lower, and the unfermented VFA (primarily acetate, propionate and butyrate) remain available for absorption through the rumen wall, to serve as primary sources of energy and biosynthetic precursors for the host animal. Acetate serves primarily as a source for synthesis of lipids (including milk fat in the mammary gland). Propionate serves primarily as a substrate for gluconeogenesis in the liver. Butyrate serves primarily as an energy source for the absorptive cells of the rumen epithelium.

The rumen is additionally a site of protein fermentation by some members of the microbial community. Feed proteins are, to a variable extent, hydrolyzed to peptides and amino acids, which can either be fermented by this subpopulation as a source of energy, or used as anabolic precursors by the larger microbial community. The products of protein fermentation are primarily the above-mentioned VFA and CO₂, but also ammonia, and with very little H₂ or methane. Fermentation of amino acids is carried out both by metabolic generalists that also ferment carbohydrates (e.g., *Prevotella* and *Butyrivibrio*) and by obligate amino acid fermenting bacteria (e.g., *Peptostreptococcus anaerobius*, *Clostridium sticklandii*, and *C. aminophilum*). The latter group can ferment amino acids at ten times the rate of the former, but their overall contribution to ammonia production is unclear, as they typically have very low abundance in the rumen. Although the ruminal community can synthesize large amounts of microbial cell protein from ammonia and VFA and thus recapture some of the protein lost to fermentation, the process of protein utilization in the rumen results in a net loss of feed protein, and thus contributes to the substantial inefficiency of N utilization by ruminants.

On the whole, then, the rumen can be regarded as an essential organ in which feeds that cannot be used directly by the host are converted to VFA, the usable currency for energy metabolism for the host animal. VFA production allows the ruminal fermentation to maintain its redox balance in a habitat where electron acceptors are generally lacking (CO₂ being a major exception). The overabundance of readily oxidizable organic matter in the ruminant diet also facilitates ready utilization of other electron acceptors that may become available, including unsaturated fatty acids (reduced to their corresponding saturated fatty acids); nitrates and nitrites (reduced to ammonia); and sulfate (reduced to sulfide, which at elevated levels can cause the neurodegenerative disease, polioencephalomalacia).

Culturable and Uncultured Ruminal Microorganisms

The development by Hungate and others in the 1940s of effective techniques for cultivating strictly anaerobic bacteria led to the isolation and characterization of many ruminal bacterial species that, in total, appeared to represent a substantial portion of the fermentative capabilities of the ruminal community. These isolates allowed microbiologists to elucidate the biochemical pathways of these fermentations and to quantify fundamental parameters such as growth yields and maintenance requirements. They also permitted, through studies of mixed cultures of defined species composition, the elucidation of metabolic interactions among these species. As it turned out, however, there was much more to the story.

By the late 1970s, fundamental studies on microbial phylogeny, gained largely through sequence analysis of chromometric macromolecules such as small-subunit ribosomal RNAs, revealed that species diversity in all microbial habitats was far greater than had been anticipated from studies that employed only culture-based methods. In some habitats, particularly low-nutrient ones such as pristine groundwater or oligotrophic lakes, fewer than 0.01% of the microbial population could be cultivated in the laboratory. For the rumen, it appears that the percentage is much higher – on the order of 10%. Even so, it is clear that the vast majority of the ruminal microbial community has resisted laboratory cultivation. So, while much of the metabolic activity of the rumen can be understood from earlier studies with cultured representatives of the community, elucidating the characteristics and capabilities of the larger, uncultivated community members is likely to provide a trove of new information that will inform our understanding of ruminal metabolism.

Bacteria are the most numerically dominant members of the ruminal microbiome, accounting for $\sim 10^9$ – 10^{10} cells mL⁻¹ of ruminal fluid. Analysis of community composition using the techniques of molecular ecology is confounded somewhat by methodological issues, such as community DNA extraction method, PCR primer sequences, sequencing platform, and downstream bioinformatics package. Consequently, it is difficult to compare community compositions across studies. Nevertheless, some general trends on community composition have emerged. It is clear that the two most abundant bacterial phyla in the rumen are the Firmicutes and Bacteroidetes. The Firmicutes are dominated by the order Clostridia, particularly the genera *Butyrivibrio*, *Ruminococcus*, *Lachnospira* and *Succiniclaticum*. The Bacteroides are heavily dominated by the genus *Prevotella*, which may represent half or more of the individual bacteria in the rumen.

Archaea are much less abundant than bacteria ($\sim 10^7$ – 10^8 cells mL⁻¹), and consist almost entirely of methanogens. The hydrogenotrophic genus *Methanobrevibacter* is by far the most dominant genus, although there are significant abundances of the little-studied methylotrophic family Methanomassiliicoccaceae.

Protists (often called protozoa) are much less abundant than bacteria (10^5 – 10^6 cells/mL), but because of their large size (10–100 μ m) can comprise 40% or more of total ruminal microbial biomass. The two most abundant groups in the rumen are the entodiniomorphs and the isotrichids. Both are motile via cilia, though the distribution of the cilia differs between the groups. Entodiniomorphs have tufts of cilia, and those near the mouth aid in engulfment of particulate matter – bacteria, starch granules, fiber and insoluble protein – that support protozoal growth. The engulfment and fermentation of bacteria and feed proteins result in ammonia production and contribute to nitrogen inefficiency in the host animal. On the other hand, the entodiniomorphs assist

in fiber degradation, and their engulfment of starch and its subsequent slow fermentation decreases the much more rapid degradation of starch by bacteria that can lead to lactic acidosis. The other major protozoal group, the isotrichids, have cilia evenly distributed on the cell surface, and subsist primarily on soluble sugars. When sugar is abundant, the isotrichids produce and store massive amounts of glycogen, often rendering the cells opaque. Isotrichids are also thought to assist in maintenance of anaerobic conditions in the rumen, as they can respire oxygen, albeit without coupling the respiration to ATP synthesis. Some protozoa harbor endosymbiotic methanogens (discussed in more detail below) and thus are indirect contributors to ruminant enteric methane production.

Ruminal fungi were originally thought to be protozoa, due to the presence of a motile zoospore stage, but their fungal nature was revealed by their chitin-containing cell walls; their filamentous growth habit during their non-motile stage; and, ultimately, their 18S rRNA gene sequences. While not particularly abundant (10^3 – 10^4 cells mL⁻¹), these fungi appear to be important in degrading plant cell wall material via a combination of physical splitting of fibers by growing appresoria (exposing fibers for bacterial colonization), and by production of small amounts of high-specific activity polysaccharide hydrolases. The ruminal fungi are presently restricted to family Neocallimasticaceae within the primitive, anaerobic phylum Neocallimastigomycota. Assessment of phylogenetic diversity within the fungi is complicated by the limited sequence diversity within the small-subunit rRNA genes, but examination of internally transcribed sequences between rRNA genes has revealed extensive diversity within the fungal group.

While the above characterizations of the ruminal community are averaged across the whole of the rumen, there are substantial differences in the community compositions of the solid phase (which contains feed particles in the process of degradation) and the liquid phase of ruminal contents. Samples collected directly from the rumen through a ruminal fistula are considered the gold standard for community composition analysis, as they allow for representative sampling of the rumen and separate analysis of the liquid- and solids-associated communities. Samples collected by stomach tubing or by buccal swabbing are more enriched in the liquid-associated community, but methodological improvements (such as directly hand-capturing the cud, or buccal swabbing during periods of active rumination) are likely to improve representative sampling, and thus allow analysis of a larger number of animals than would be possible by relying purely on fistulated animals.

In addition to the solids- and liquid-associated microbial communities, there is an important but relatively unstudied epimural community that is attached to the interior of the rumen wall. This community is the interface between the ruminal liquid phase and the ruminal epithelial cells that are involved in uptake of VFA, NH₃, CO₂ and other metabolites into the host circulatory system. Community analysis reveals that, relative to the liquid and solid phases of ruminal contents, the epimural community is underrepresented in genus *Prevotella* but overrepresented in *Butyrivibrio*, consistent with the importance of butyrate as a primary energy source for the ruminal epithelial cells.

Microbial community analyses have revealed that microbial taxa that are abundant in feeds are much less abundant in the rumen itself. For example, lactic acid bacteria such as *Lactobacillus* or *Enterococcus*, that are the dominant bacteria in silages, are essentially undetectable even in the rumens of cows fed silage as the main component of their diet. This is a powerful demonstration that ruminal conditions select against nonruminal microbes, even those from plant-based anaerobic habitats. However, some transient species can still be problematic for human and animal health. For example, the rumen is a known reservoir for low populations of enteropathogenic *E. coli*, and it has been shown that feeding of too much grain (which decreases ruminal pH) activates acid resistance in these pathogens; upon shedding from the ruminant GI tract, these strains are more able to survive passage through the acid stomach of human hosts, and thus more capable of colonizing the lower GI tract, where they can cause severe – and even fatal – toxicoses.

Interactions Among Ruminal Microbes

Negative Interactions: Competition, Amensalism and Predation

The ruminant diet, despite its complexity, contains a relatively modest number of fermentable monomeric components. Because the utilization of these substrates is distributed across a large number of different microbial species, it is inevitable that there is intense competition among these species for these substrates. There appears to be a relationship between the metabolic capabilities of the fermentative organisms and the abundance of the substrates. Widely available substrates such as glucose can be used by a large number of catabolically versatile species, while less abundant substrates (e.g., plant toxins such as mimosine or oxalic acid) are metabolized by a relatively small number of metabolic specialists.

Competition, an interaction in which there is a simultaneous inhibition of two organisms based on their shared utilization of a common substrate, is governed by the concentration of substrate and by the relative abundance and metabolic activity of the individual microbial species, including their maximal rates of substrate utilization and their saturation constants. Analysis has revealed that utilization rates for most substrates follow Michaelis–Menten kinetics, and are typically first-order with respect to substrate concentration. In the case of insoluble biopolymers (e.g., cellulose), degradation rates appear to depend on the accessible surface area. The most abundant and capable of the cellulolytic species require adherence to cellulose for effective hydrolysis (Fig. 1), so the outcome of competition is driven primarily by an organism's ability to rapidly colonize cellulose fibers as they are exposed by rumination.

Amensalism, an interaction based on the inhibition of one organism by another, occurs in the rumen via production of bacteriocins. Most bacteriocins are small, membrane-permeabilizing proteins that often show a high degree of specificity – some times inhibiting only closely related species or even other strains within the same species. While most studies of bacteriocins have been carried out using

Fig. 1 Light microscopic image of three particles of microcrystalline cellulose colonized by cells of the ruminal cellulolytic bacterium *Ruminococcus albus* 8 (visualized here by staining with crystal violet dye). Effective cellulose hydrolysis requires adherence of the cells to the particles, and the adherent bacteria far outnumber the non-adherent (planktonic) cells, which will likely colonize an exposed cellulose surface upon contact. Physical adherence to cellulose allows the cellulolytic cells first access to the soluble products of cellulose hydrolysis, and helps them to compete effectively with the many saccharolytic but non-cellulolytic species within the diverse community of the rumen.

common intestinal bacteria such as *E. coli*, most of the known bacteriocin producers in the rumen are Gram-positive members of the Firmicutes, particularly within the genera *Butyrivibrio*, *Streptococcus* and *Ruminococcus*.

Predation of microbes in the rumen primarily involves engulfment of bacteria by flagellated and ciliated protists (protozoa). Feeding appears to be non-specific. The net result is that hard-won microbial protein is degraded by the ingesting protozoa, thus reducing the N efficiency of the ruminal fermentation. Artificial removal of protozoa from the rumen (a process termed 'defaunation') can be accomplished with certain chemical agents (e.g., alkanes or lauric acid), but the effects on animal performance have been somewhat contradictory. In general, defaunation decreases the wasteful process of methanogenesis and improves N efficiency, but can also result in decreased fiber digestion. Moreover, these effects gradually disappear over time (~10–12 wks) as the protozoa slowly recolonize the rumen. While protozoa are the primary agents of predation in the rumen, shotgun metagenomics sequencing of ruminal contents have revealed the presence of an extensive viral community, and also the presence of predatory bacteria such as *Vampirobacter*. The quantitative importance of these groups remains to be elucidated.

Mutualistic Interactions

Mutualistic interactions, in which both partners benefit from the association, are common in the rumen (Fig. 2). The best-known example is 'interspecies hydrogen transfer' (IHT), which was first characterized in the rumen but has subsequently been shown to be widely distributed in anaerobic habitats. In IHT, the H_2 produced by a fermentative microbe is used as an electron donor and energy source for a H_2 consuming microbe (methanogenic archaea, sulfate-reducing bacteria, etc.). The H_2 consumer obviously benefits from the availability of the electron donor. The H_2 producer benefits because continuous removal of H_2 permits enhanced flux of

Fig. 2 Examples of interactions among trophic groups in the rumen. Major dietary inputs are in square boxes; major terminal end products are in oval boxes. Key intermediates that do not typically accumulate are in grey type. Exemplary microbial species or groups are in blue. The straight-chain C_4 – C_6 VFA butyrate (shown) along with valerate, and caproate (not shown) are synthesized primarily via reverse β -oxidation by *M. elsdenii*, among others.

reducing equivalents toward the reduction of protons to H_2 ($2 H^+ + 2 e^- \rightarrow H_2$). This allows the fermentative bacterium to channel more carbon-containing catabolic intermediates toward production of acetate (a pathway that generates more ATP for growth) rather than toward production of reduced intermediates such as lactate or ethanol (pathways that have lower net ATP yields). A particularly interesting type of IHT occurs between carbohydrate-fermenting holotrich protists and endosymbiotic methanogens. Pyruvate produced by the protozoa is translocated to a specialized intracellular organelle, the hydrogenosome, where the pyruvate is converted to acetate, CO_2 , and H_2 . The H_2 diffuses through the hydrogenosome membrane, where the endosymbiotic methanogens hungrily await. The phenomenon can be visualized under a fluorescence microscope, due the autofluorescence of F_{420} electron carrier within the methanogenic cells.

The microbial use of another microbe's fermentation products in the rumen extends well beyond IHT. Succinate is an important intermediate in carbohydrate fermentation by some ruminal bacteria, such as *Fibrobacter succinogenes*, *Ruminococcus flavefaciens*, *Prevotella bryantii*, and *P. brevis*. However, succinate is rarely detected in ruminal fluid, due to the activity of succinate-fermenting bacteria such as *Selenomonas ruminantium* and *Succiniclasticum ruminis*, which decarboxylate succinate to produce propionate. It has been estimated that approximately half of the propionate produced in the rumen is derived from succinate decarboxylation (the other half is derived from conversion of lactate, via acrylate as an intermediate).

Cross-feeding of nutrients is not restricted to energy sources. One well-documented example involves peptide- and amino acid-fermenting bacteria and cellulolytic bacteria (Fig. 1). The former produce the branched-chain volatile fatty acids (BCVFA) isobutyrate, 2-methylbutyrate and isovalerate, which are required for synthesis of lipid precursors (long, branched-chain fatty acids) by the primary cellulolytic bacteria *Ruminococcus albus*, *R. flavefaciens* and *Fibrobacter succinogenes*.

The ruminal microbial community is also important as a producer of vitamins needed by the host animal. These include the common water-soluble vitamins as well as the fat-soluble vitamin K. Production levels are typically sufficient to meet the needs of the host, so in conventional ruminant rations only vitamins D and E are required. Many individual species of ruminal microbes require the water-soluble vitamins, but their needs are met via overproduction by other members of the microbial community.

Redundancy and Resilience of the Ruminal Microbial Community

As noted previously, there are likely hundreds of individual species of ruminal bacteria, based on community analyses of rRNA gene sequences in bulk ruminal contents. By contrast, there are likely a smaller number of potential fermentable substrates or hydrolyzable polysaccharide linkages. Simple division allows us to conclude that, on average, there are multiple species capable of exploiting any particular "degradation point", and many substrates such as glucose, are likely degradable by many dozens of species. Moreover, many ruminal species are catabolically versatile, being capable of fermenting dozens of substrates. On the whole, then, the ruminal community displays considerable overlap of metabolism, or a high degree of 'functional redundancy'. As a result, the ruminal community is less dependent on individual members, because if one such species should disappear, other community members, either individually or collectively, are likely able to assume the functional role of the displaced member. In fact, despite the large variation in the abundance of individual microbial species across individual animal units fed similar diets, there is a striking similarity in the proportions of the various fermentation products, i.e., there appears to be a distinct convergence of function among different communities.

Ruminal communities from individual cows display temporal variation in composition, particularly during the feeding cycle. Soon after feeding, rapidly fermented substrates are metabolized to yield organic acids at rates that outpace the ability of the host to absorb them, or the ability of salivary buffers to neutralize them. Nevertheless, despite these temporal variations, each rumen has a relatively unique range of microbial species compositions. This community displays remarkable resilience, as shown by the fact that near-total (~95%) exchange of ruminal contents across animals results in a gradual return, over days to weeks, to approximate the pre-disturbed composition. Some of this resilience is likely due to inherent differences in ruminal chemistry between animals (e.g., in pH dynamics or VFA concentrations), but the resilience has also been observed following exchanges in ruminal contents between animals having similar ruminal chemistries.

The redundancy of the ruminal community explains the behavior and usefulness of in vitro ruminal fermentations. Such fermentations are widely employed to assess the fermentability of feeds and feed components; to compare the digestibility of different forage cultivars; or to test the effects of ruminal modification agents. In vitro fermentations do not benefit from continuous VFA removal or from continuous salivary buffering, as occurs in the live animal. Consequently, in vitro fermentations can be viewed as a type of enrichment culture, and – as in all enrichment cultures – the species composition of the community begins to change immediately following inoculation. Nevertheless, the outcome of the fermentation, in terms of product distribution and microbial cell yield, is remarkably similar to that observed in the rumen itself. This is likely due to the above-mentioned convergence of function among the many species in the rumen, such that taxa which are enriched under in vitro conditions produce fermentation end products in similar proportions to the taxa they outcompete in vitro.

Community Development and Host Individuality

At birth the ruminant animal lacks a functional rumen, and from a nutritional standpoint resembles the non-ruminant animal in that nutrients are derived primarily from colostrum, and soon thereafter from milk. The rumen develops slowly over about a

two-month period, stimulated largely by a gradual increase in intake of solid feeds, including fibrous feeds. These anatomical and digestive changes are accompanied by dramatic changes in the composition of the microbial community. Although the 3 most abundant bacterial phyla are Firmicutes, Bacteroidetes and Proteobacteria, regardless of age group, the proportion of the different genera comprising these phyla change in an age-dependent manner. During the first few days after birth, the community is dominated by taxa associated with aerobic or facultatively anaerobic metabolism, including the genus *Bacteroides*. Over a period of about two weeks, the community shifts toward one dominated by strictly anaerobic bacteria; the genus *Prevotella* becomes numerically dominant, and this dominance is retained into adulthood. Compared to the mature rumen of a 2-year old animal, calves at 1 d and 3 d of age show less diversity and a greater degree of inter-animal variation in bacterial community composition than do the animals at 2, 12, or 24 months. It is notable, however, that some taxa that are abundant in the adult rumen make their initial ruminal appearance within a few days of birth. One particular example is the genus *Ruminococcus*, most of whose members are considered to be cellulolytic, but whose ruminal appearance long precedes the ingestion of fiber.

Protozoa are not found in newborn calves, and often do not make their appearance until the animals reach several months of age. Protozoa can be established earlier by direct inoculation of calves with ruminal contents (or cud samples) from adult ruminants.

Although the bacterial communities of different animals on the same diet converges somewhat in species composition over time, adult ruminants do maintain microbial communities that are generally individualized to the host. This individuality is most clearly reflected in ruminal contents exchange experiments, as described in the previous section.

Community Responses to Ruminal Environmental Conditions

Response to Dietary Inputs

Surveys of ruminal microbial communities across host species and geographic regions have indicated that diet is the main driver of ruminal bacterial composition, overriding differences between individual animals, breeds within ruminant species, and even ruminant species themselves. Different diets select for variations in the proportions of individual bacterial species, and their differential use of particular fermentation pathways results in end product ratios that profoundly affect animal performance. Diets rich in soluble sugars and starch, particularly in rapidly fermentable forms such as finely ground high-moisture corn or barley, yield lactate as a major primary fermentation product, and subsequent conversion of this lactate to propionate results in the characteristically low ratio of acetate:propionate (A:P) observed under these feeding conditions. Protist community composition does not appear to show as much dependence on diet as do the bacteria, perhaps because of their predatory lifestyle and/or nonspecific feeding behavior. Fungal populations in the rumen are generally low (~1% of total microbial biomass) in ruminants fed diets rich in concentrates or in forages from temperate regions, but are five-fold or more higher in ruminants grazing tropical forages. This is likely the result of the important role fungi have in physically splitting and enzymatically depolymerizing the more heavily lignified and recalcitrant cell walls in tropical forages.

While the microbial communities in forage-fed ruminants differ substantially from those fed primarily concentrates, it has proven difficult to identify more than a few genera that differ consistently with diet. It does appear that the most abundant genus, *Prevotella*, is even more abundant in concentrate-fed animals, while forage-fed animals show greater abundance of *Fibrobacter* and unclassified members of the Ruminococcaceae and Bacteroidales families. Within individual studies, it is apparent that even minor changes in diet can have observable effects on community composition. For example, a seemingly modest shift in grazing dairy heifers from orchardgrass pasture to orchardgrass hay results in an increase in the molar percentage of acetate and a decrease in the molar proportion of butyrate, along with a decrease in the abundance of *Butyrivibrio*, the major butyrate producer in the rumen.

Response to Ruminal pH

After feed composition, pH is arguably the most important effector of the ruminal fermentation. Ruminants evolved as grazing animals, during which they largely subsisted on forages whose bulk limited intake, and whose composition and structural anatomy resisted rapid fermentation. In most grazing ruminants, ruminal pH remains in the range of 6–7 most of the time, and this pH range seems ideal for most ruminal microbes. The introduction of grains and other rapidly fermented concentrates to the diets of domesticated ruminants has resulted in greater dry matter intakes and more rapid fermentation of carbohydrate and protein, and as a result mean ruminal pH can be relatively low (sometimes less than 5), and diurnal pH range can be substantial. Individual ruminants fed the same diet can vary substantially in mean pH and diurnal pH range, due in part to differences in meal patterning; volume of buffering saliva secreted; and efficiency of VFA absorption by the ruminal epithelia.

In general, carbohydrates such as sugar monomers and dimers, as well as highly processed starches (such as milled barley and finely ground high-moisture corn) are fermented more rapidly than resistant starches or plant cell walls rich in cellulose and hemicelluloses. The agents of such rapid fermentation include *Prevotella* species, *Streptococcus bovis* and *Selenomonas ruminantium*. *S. bovis* has been widely considered as a major producer of lactic acid, which is a much stronger acid than are the VFA (pK_a 3.8 versus 4.8). Because lactate is consumed relatively slowly in the rumen, its production in quantity can substantially decrease ruminal pH, sometimes to values below 4.5. The resulting acute lactic acidosis can disrupt ion balances in the rumen, and if imported into the bloodstream can cause a dangerous drop in blood pH. Interestingly, *S. bovis* is barely detectable in the rumen of cows under normal conditions, and its abundance even under acidotic conditions is not particularly high, suggesting perhaps that *S. bovis* can be highly

active but produces only a low cell yield, or that other bacteria may contribute to lactic acidosis. Ruminal acidosis is not only caused by lactic acid accumulation. Some cows that display chronically low ruminal pH do not contain measurable amounts of lactate, but do contain high concentrations of VFA (up to 0.25 mol L^{-1}), and often do not produce adequate amounts of saliva to effectively buffer ruminal pH; such cows often have ruminal dry matter contents of 18% or higher.

Certain members of the ruminal microbial community appear to be particularly sensitive to low pH. The predominant species of cellulolytic bacteria do not grow at pH values below 6.0. However, pH values below this minimum do not kill these bacteria, but rather arrest their growth, without inhibiting their cellulases. Thus, even in animals with atypically low pH values, fiber digestion is not inhibited as long as pH remains above 6.0 for long enough during the feeding cycle to allow the bacteria to grow at rates exceeding the average dilution rate of the solid portion of ruminant contents (to which the cellulolytic bacteria are attached). During the time period when pH is below 6 and cellulose hydrolysis is still occurring (albeit at a decreased rate), certain acid-tolerant noncellulolytic bacteria become the primary agents of fermentation of cellodextrin oligomers. As it happens, many of these species produce lactate, whose conversion to propionate results in an observed decrease in acetate:propionate ratio, a key effector of nutrient delivery to the host.

A second relatively acid-sensitive microbial group in the rumen is the methanogenic archaea. These organisms also grow poorly below pH 6, and this property is thought to be a major reason that ruminants fed diets high in concentrates produce lower amounts of enteric methane than do forage-fed ruminants.

Response to Toxic Compounds

Many plants produce anti-nutritive compounds to discourage consumption by animal and arthropod herbivores. Ruminants can often develop tolerance to these plant metabolites, primarily through the adaptation of the ruminal microbiota to metabolize these compounds. A classic example involves production of mimosine by the tropical legume, *Leucaena leucophila*. Mimosine is a non-protein amino acid that is metabolized to 3,4-dihydropyridine (3,4-DHP), a potent goitrogen. As a result, consumption of *Leucaena* by ruminants was problematic, until it was discovered that a certain herd of feral goats in Hawaii could consume this legume with impunity. The resistance was traced to the presence of a novel specialist ruminal bacterium (since named *Synergistes jonesii*), that could metabolize both mimosine and 3,4-DHP. Inoculation of ruminal contents from these goats, or with a pure culture of *S. jonesii*, conferred mimosine tolerance to other ruminants, including sheep and cattle.

A second example of bacterial detoxification is presented by oxalic acid. This small dicarboxylic acid (HOOC-COOH) can accumulate in some xerophytic plants (up to 40% of dry matter in the noxious weed, *Halogeton glomeratus*). Oxalate is a potent chelator of calcium, and upon ingestion can induce severe hypocalcemia in sheep or other livestock. Gradual adaptation to halogeton results in proliferation of *Oxalobacter formigenes*, a specialist bacterium whose sole known catabolic pathway is the dismutation of oxalate to formic acid (HCOOH) and CO_2 .

Metabolism of plant toxins is not restricted to native microbial species. Inoculation of sheep with a recombinant strain of *Butyrivibrio fibrisolvens*, engineered to contain a *Moraxella* dehalogenase enzyme, has been shown to confer resistance to plants containing the potent TCA cycle inhibitor, fluoroacetate. Subsequent searches have revealed the presence of natural fluoroacetate-metabolizing bacteria in some Brazilian ruminants.

A common characteristic of these plant toxin-degrading bacteria is that their substrates (the plant toxins) are low molecular weight compounds that are produced abundantly in their plant hosts, and that are degradable by very short metabolic pathways. These characteristics have likely hastened the evolutionary development and maintenance of these pathways. By contrast, robust degradative pathways do not appear to have yet developed for compounds such as peroline or lysergic acid alkaloids (produced by mycorrhizal fungi associated with tall fescue, an important pasture grass in the southeastern USA); these potent poisons are more structurally complex and are produced in only small amounts, thus providing less selective pressure for development of microbial degradative pathways. However, given the high degree of adaptability of microbes and the large number of available habitats (i.e., the large number of individual ruminant animal units), the eventual development of such degradative pathways cannot be ruled out.

Prospects for Manipulating the Ruminal Microbiota

The desire to direct the ruminal community toward specific host physiological outcomes has long enchanted both microbiologists and animal scientists. In particular, there are substantial motivations from economic, social and environmental standpoints in three specific manipulations: Mitigation of methanogenesis; improvement in efficiency of feed utilization (especially nitrogen utilization); and improved utilization of low digestibility feeds (especially forage fiber). In addition, there has been substantial interest in introducing non-native probiotic microbial strains into the rumen to address the proposed manipulations, as well as others. The practicality of all such manipulations must be viewed through careful consideration of the principles of microbial ecology.

Methane Mitigation

Efforts to decrease enteric methane production are driven by the fact that animal agriculture accounts for ~15% of anthropogenic production of methane, a greenhouse gas much more potent than CO_2 . As noted above, ruminal production of methane almost

exclusively proceeds via oxidation of H_2 with CO_2 as electron acceptor. Attempts to divert H_2 oxidation to other pathways have primarily focused on reductive acetogenesis ($4 H_2 + 2 CO_2 \rightarrow CH_3COOH$), as the electron acceptor (CO_2) is already abundant, and the product acetate contributes to host nutrition as a lipid precursor and energy source. Although acetogens capable of the above reaction are found in low abundance in the rumen, they do not appear to produce significant amounts of acetate from the above reaction. The reasons for this appear to be both thermodynamic (lower energy yield than methanogenesis) and kinetic (lower affinity for H_2 by the acetogens' hydrogenase, when compared to the methanogens). Instead, these versatile acetogenic bacteria are likely metabolizing other energy sources (methoxylated plant components or carbohydrates) rather than H_2 . Diverting H_2 oxidation toward other microbes also appears to be of limited practicability, due the requirement for feeding large (stoichiometric) amounts of alternative electron acceptors (e.g., nitrate, fumarate, or Fe^{+++}), and have been only partially successful under both in vitro and in vivo conditions. A more promising strategy may be targeted inhibition of enzymes involved in the methanogenic pathway; the compound 3-nitrooxypropanol appears to be particularly effective. Disruption of these pathways should allow a redistribution of reducing equivalents into other fermentation products (particularly propionate and butyrate, via existing metabolic pathways) whose production would provide energy to the host animal.

Improving Nitrogen Utilization Efficiency

The main motivation for domesticating ruminant animals was to harness their ability to convert low-quality forage and browse plants to proteins useful to their keepers, in the form of meat, milk and wool. The protein in the plant materials – often low in quality and quantity – were augmented with microbial cell protein synthesized by the ruminal microbial cells. This microbial cell protein was produced using amino acids from the original plant proteins, as well as from microbial anabolic reactions in which organic intermediates were combined with ammonia released from urea cycling and from amino acid fermentations in the rumen. As agriculture intensified over the last century, feeding of concentrated protein sources has helped improve production of ruminant animal protein. However, nitrogen utilization efficiency in ruminants has remained poor (e.g., less than 25% of the protein fed dairy cows is recovered in the milk, with most of the rest lost in manure). Many feed proteins are extensively fermented in the rumen before they can pass to the intestines. Moreover, a substantial fraction of proteins synthesized *de novo* by ruminal bacteria is lost due to protozoal predation on bacteria, and the resulting fermentation of amino acids by the protozoa yields ammonia, whose re-assimilation by bacteria is energetically costly.

Attempts to improve N utilization efficiency have focused on any of several strategies: (1) treatment of feeds to make them less degradable in the rumen (e.g., soybean roasting); (2) enhancing ruminal availability of readily utilizable carbohydrate to facilitate microbial protein synthesis; (3) decreasing density or activity of protozoa that ingest bacterial cells and ferment their protein; and (4) inhibiting microbial proteases or amino acid fermentations in the rumen. Of these, the last approach involves microbial activities most directly, but has proven the hardest to exploit, likely because of the large variety of proteolytic and amino acid-fermenting microbes (i.e., the functional redundancy of the microbial community).

Improving Fiber Digestibility

Many forages, particularly from tropical regions, are poorly digestible due to extensive lignification, high ash content, or the presence of anti-nutritive compounds. Regardless, even the most digestible forages are digested more slowly than are most grains and other feed concentrates. The rate-limiting step in the digestibility of most forages is the complex structure of polysaccharides in the plant cell wall. As noted in the Introduction, the ruminant animal uses the process of rumination to expose the degradable surface of cell wall polysaccharides to enzymatic and microbial attack. Digestibility of cellulosic feeds in vitro can be enhanced by grinding the feeds to a smaller particle size, but such an approach is not practical in vivo because it accelerates passage of the particles from the rumen, before they can be fully degraded. Chemical pretreatments can improve digestibility both in vitro and in vivo, but are inconvenient, costly, and often introduce waste disposal problems. As a result, there has been considerable interest in stimulating the microbiota to degrade forage fiber more effectively and completely. In practice, this has proven to be difficult, because the rate-limiting factor is substrate accessibility, not microbial numbers or microbial capabilities. This can readily be demonstrated by measuring rates of fiber degradation in vitro. Dilution of ruminal fluid does not decrease the rate of cellulose digestion in vitro until dilutions exceed 5- or 6-fold. Limitation by substrate is also shown by the fact that its digestion kinetics remain first-order with respect to substrate concentration. Because the process of fiber digestion is limited by substrate, improving the numbers, density or activity of the fibrolytic microbes are unlikely to improve fiber digestion, except if the microbes could disrupt specific linkages in the plant cell wall that would improve substrate accessibility.

Probiotics

Probiotics (sometimes called direct-fed microbials, DFM) are living microorganisms that enhance the health of the host animal after they are consumed. Probiotics are widely employed, with variable success, in humans and in non-ruminant domestic animals (e.g., swine and chickens). Successful probiotics demonstrate at least limited persistence in the host. The use of probiotics in ruminants is more sporadic, due in part to the challenge of effectively persisting in the rumen or in competing with the indigenous microbes of the rumen and/or hindgut. Indeed, few controlled studies with probiotics have included measurement of their persistence within the host animal. The mechanisms by which probiotics exert beneficial effects are not always apparent, and it likely that elucidation of these mechanisms will guide development of more effective probiotics.

Introduction

Biothreats gained renewed attention as a result of the 2001 anthrax letter attacks. Less than a month after 9/11, a deliberate act of bioterrorism was committed by using the United States Postal Service as a dissemination vehicle to intentionally disperse *Bacillus anthracis* spores along the eastern seaboard, ranging from New York to Florida [Bush et al., 2001](#); [Hsu et al., 2002](#); [Jernigan et al., 2001](#); [Jernigan et al., 2002](#); [Keim et al., 2011](#); [National Research Council, 2011](#); [Popović & Glass, 2003](#); [Traeger et al., 2002](#). Letters were mailed to two senators, news anchor Tom Brokaw of NBC News, and the *New York Post*, each containing *B. anthracis* spores [Hsu et al., 2002](#); [Keim et al., 2011](#); [National Research Council, 2011](#). The attack resulted in 22 infections, of which five deaths occurred, and caused substantial disruption across the nation [Jernigan et al., 2002](#); [Keim et al., 2011](#); [National Research Council, 2011](#). Although biological weapons and the threat of their use as biowarfare, bioterrorism, and biocrimes have been employed throughout history, this act of bioterrorism spread new fears among the nation. Some of the earliest known cases using biological threats can be traced back thousands of years. The Romans used to contaminate their enemies water supplies with decaying animal carcasses [Budowle et al., 2005a](#). In the fourteenth century, in the battle of Kaffa, Tatar soldiers threw the bodies of their infected dead over the walls of the city to infect the enemy with plague [Christopher et al., 1997](#). Biological warfare has been used in wars such as the French and Indian war, WWI, and WWII, and a number of countries, including the United States, have had offensive biological warfare programs [Christopher et al., 1997](#). Biological agents also have been used as weapons in cases, known as biocrimes, in recent history. For example, in 1984 followers of the Baghwan Sri Rajneesh cult intentionally contaminated local salad bars with *Salmonella typhimurium* in Dalles, Oregon hoping to influence the results of a local election; this biocrime resulted in 751 infected individuals [Török et al., 1997](#). In 1996, a Dallas, TX hospital laboratory technician intentionally contaminated muffins with a laboratory stock of *Shigella* and placed them in a breakroom; 12 people were infected, four of which were hospitalized [Kolavic et al., 1997](#). Anthrax, the disease caused by the bacterium *B. anthracis*, is probably the most infamous biothreat agent. *B. anthracis* spores were disseminated in Tokyo by the Aum Shinrikyo Japanese cult in 1993; luckily, no infections resulted as the spores were of the Sterne strain, a vaccine strain [Keim et al., 2001](#). In contrast, the Ames strain, a strain not commonly found endemically in the United States, was used in the 2001 anthrax letter attacks [Budowle, 2004](#). Biological agents that may cause harm can be relatively cheap, easy to obtain, and require little sophistication to disseminate compared with other forms of weapons of mass destruction. The historical and recent use of biological weapons demonstrates the continual threat of their use in cases of bioterrorism and biocrimes.

The 2001 anthrax attacks demonstrated the degree of fear, disruption and damage that can occur from a relatively small attack by contamination with only a handful of spore-laden letters. In addition, the investigative time and costs associated with the attack were substantial. The anthrax letter investigation, termed Amerithrax by the FBI (Federal Bureau of Investigation) [National Research Council, 2011](#), spanned nearly a decade with an estimated economic impact of \$6 billion [Ellis, 2014](#), of which \$320 million was associated with decontamination costs [Schmitt & Zaccchia, 2012](#). In 2001, the US government, public health service, and law enforcement agencies were largely unprepared for such an event, and the realization became evident of how vulnerable the country was to such an attack [Breeze et al., 2005](#); [Budowle et al., 2011](#). Although, prior to 2001 a need for an established microbial forensics field was predicted, a formal system had not been implemented [Murch, 2003](#). As a result of the 2001 attack, the microbial forensics field was officially launched by necessity [Breeze et al., 2005](#); [Budowle et al., 2003](#); [Budowle et al., 2005b](#); [Budowle et al., 2005c](#); [Budowle et al., 2006](#); [Budowle et al., 2011](#); [Morse & Budowle, 2006](#); [Murch, 2003](#). Microbial forensics is the discipline of applying scientific methods for analyzing evidence from a bioterrorism attack, biocrime, hoax, or inadvertent release of a biological agent or toxin with attribution as the ultimate goal [Budowle et al., 2003](#). Attribution of microbial evidence is to determine an associated source and perpetrator or group of individuals to the highest degree possible. The microbial forensics field is an interwoven network of scientists from multiple specialties (i.e., microbiology, genetics, bioinformatics, forensic science, immunology, population genetics, biochemistry, molecular biology, epidemiology, etc.) and the law enforcement, public health, policy, and intelligence communities.

Microbial forensic investigations center on the detection and characterization of both biological agents, in addition to non-biological evidence. Biological agents consist of bacteria, viruses, protists, fungi, and toxins. Non-biological evidence, such as additives, growth media, delivery devices, intelligence, etc., can be useful in microbial forensics, potentially providing investigative leads and helping to infer methods of manufacture and dissemination [Velsko, 2011](#). Non-biological evidence analysis is an integral part of microbial forensics; however, the focus of this chapter is on the biological analytical methods. Microorganisms and their

[☆]*Change History:* August 2014. S Schmedes (new author) and B Budowle prepared the Microbial Forensics chapter with the following changes: updated the Abstract and keywords; updated the introduction and modified Figure 1; added a new table; added the section 'Forensic and Epidemiological Investigations'; updated the 'Detection and Identification Capabilities' section (and changed the section title to 'Detection, Characterization, and Emerging Technologies') and added new subsections with new specific focus topics; updated the 'Interpretation of Microbial Forensic Results' section; updated the 'Conclusions' section.

This article is an update of S.Y. Hunt, N.G. Barnaby, B. Budowle, S. Morse, Forensic Microbiology, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 22–34.

toxins are desirable weapons as they are relatively cheap to culture, can be easy to procure if endemic or occur naturally, and for many only small amounts of biological material can cause infection or even death. There is a wide variety of microbial species or strains that could serve as possible biotreats (human, plant, and animal pathogens). Indeed, over 1400 microbes are known to infect humans Taylor et al., 2001, although some are more harmful than others. However, microorganisms of the highest concern regarding public health and national security are listed as NIH NIAID (National Institutes of Health, National Institute of Allergy and Infectious Diseases) Priority Pathogens National Institutes of Health, 2013 (reviewed by the Department of Homeland Security (DHS) and the Centers for Disease Control and Prevention (CDC)) and select agents listed on the National Select Agent Registry National Select Agent Registry, 2014 (Table 1). Animal and plant pathogens also are important for biosafety and biosecurity. The agriculture and livestock industries provide substantial infrastructure to our food supply and economy. An attack on these industries can impact health, national/global economics, and political policy, as well as cause substantial disruption. For example, the 2001 foot-and-mouth disease outbreak, albeit a natural outbreak, in England had an estimated impact of more than \$12 billion Cottam et al., 2006; Ferguson et al., 2001; Thompson et al., 2002. Natural animal, plant, and food-borne disease outbreaks occur regularly causing local to wide spread infections and death and potentially cripple sectors of the food and agriculture industries. The consequences of intentional attacks can be as or more serious.

Toxins are included on the NIAID Priority Pathogens and select agents lists National Institutes of Health, 2013; National Select Agent Registry, 2014. Toxins are natural products produced by bacteria, fungi, plants, and eukaryotes. Enterotoxins, produced by different strains of, for example *Staphylococcus aureus*, are some of the most common causes of food poisoning Marks, 2011. Botulinum toxin, produced by the bacterium *Clostridium botulinum*, is a powerful toxin that is lethal even in extremely small doses Marks, 2011. One of the most accessible toxins is ricin. Ricin is derived from the castor bean *Ricinus communis* and has been used in infamous cases of assassination Audi et al., 2005; Carus, 2002; Marks, 2011. The US postal system was used again in 2003, and more

recently in April 2013, as a dissemination vehicle to send Ricin-contaminated letters addressed to the White House and other public figures Audi et al., 2005; Centers for Disease Control and Prevention, 2003; Federal Bureau of Investigation, 2013. The contaminated letters were intercepted in each case during routine mail screening and did not cause any harm Centers for Disease Control and Prevention, 2003; Federal Bureau of Investigation, 2013. The ease of access of castor beans and recipes to purify the toxin make it an easy bioterrorism to produce.

The ease and relatively inexpensive costs associated with the production and use of bioterrorism will remain an ongoing concern. Following the 9/11 terrorist attack and the anthrax letter attack, the US implemented new homeland security policies, including the formation of the Department of Homeland Security, and these new directives led to the initial policy regarding microbial forensics Pesenti, 2011. Since 2001, federal funding for civilian biodefense research (and related non-biodefense) and efforts have increased from \$414 million in fiscal year 2001 Schuler, 2004 to \$6.69 billion dollars in fiscal year 2014 Sell & Watson, 2013. Federal funding has helped initiate biodefense programs and research efforts to provide a forensic capability as well as further development of analytical tests to aid in public health and microbial forensic investigations and disease outbreak preparedness and response.

Bioterrorism used in acts of bioterrorism, biocrimes, and hoaxes are the main focus of the microbial forensics field. However, microbial forensics is used increasingly in other criminal and civil investigations, for example, in cases of disease transmission involving intentional exposure Bhattacharya, 2014; González-Candelas et al., 2013; Metzker et al., 2002; Sajantila, 2014; Scaduto et al., 2010 or sexual assault Hammerschlag & Guillén, 2010. Population genetics and phylogenetics form the bases for establishing viral or bacterial transmission in sexual assault or deliberate acts of infection with an infectious agent, such as HIV (Human Immunodeficiency Virus) Metzker et al., 2002; Scaduto et al., 2010. Phylogenetic evidence has been used in courts of law to provide interpretations regarding these types of crimes involving infectious microorganisms González-Candelas et al., 2013; Metzker et al., 2002; Scaduto et al., 2010. By constructing species and strain phylogenies and using additional information, such as times of infection, disease transmission can be inferred from one individual to another and also can be used to rule out individuals not infected by a potential source González-Candelas et al., 2013; Sajantila, 2014. Essentially microbial evidence can be used to evaluate transmission events as opposed to merely detecting the presence of a particular microorganism.

Microbial forensics is an emerging field and encompasses many specialties with collaborative efforts among scientists, public health, law enforcement, the intelligence community, and policy makers. Due to the diversity of the number of bioterrorism which potentially could be used in a bioterrorism attack or biocrime the development and validation of methods are continually ongoing as new methods are needed to address the variety of investigations that may be encountered. Therefore, it is imperative to have established standards, quality assurance guidelines, databases and biorepositories, and policy to provide the required infrastructure for a national, and even international, microbial forensic capability.

Forensic and Epidemiological Investigations

Disease outbreaks naturally occur every year throughout the world, and investigations into these outbreaks often include both epidemiology and microbial forensics investigations (Figure 1). Epidemiology studies the occurrence, features, and determinants of disease in populations. The same general principles of epidemiology for disease investigations apply to a bioterrorist attack or crime. Therefore, microbial forensics investigations are based on the same well-established principles of epidemiological investigations Butler et al., 2002; Morse & Budowle, 2006; Morse & Khan, 2005; Treadwell et al., 2003. Microbial forensics and public health share common interests regarding the identification and genetic characterization of the biological agent and how it was disseminated in the population. However, public health officials tend to focus on (1) determining that an outbreak has occurred, (2) defining the population at risk, (3) determining the method of spread and reservoir, and (4) characterizing the agent Morse & Budowle, 2006. A common thread of public health and microbial forensics is determining whether the outbreak is natural, accidental, or intentional. While microbial forensics and epidemiology are integrated disciplines, microbial forensic scientists and law enforcement concentrate on attempting to individualize the agent or toxin and how it was produced and disseminated (if applicable) for attributing the event to a person or group of persons while maintaining chain of custody for legal purposes or for decision makers and their response(s).

US public health has a well-developed system for disease outbreak surveillance. The laboratory response network (LRN) is a system of public health laboratories throughout the country designated as testing laboratories for outbreak investigations Morse et al., 2003. This system is overseen by the CDC, and it provides quality assurance guidelines and standardized protocols for pathogen detection Morse et al., 2003. In contrast, the microbial forensics field does not have a large battery of standardized methods, centralized databases or repositories. However, the National Bioforensics Analysis Center (NBFAC), part of the DHS, was created to serve as the nation's central laboratory for analysis of any bioterror or biocrime evidence Budowle et al., 2003. A single laboratory, though, cannot address all possible bioterrorism. Instead a hub and spoke model approach is employed where the NBFAC serves as the primary facility and national labs, other government agencies, academia, etc. are loosely tethered to the NBFAC to provide support as needed with testing and expertise for a quick and reliable response Budowle et al., 2003. The Amerithrax investigation was a collaborative effort of federal, private, and academic labs to develop new procedures and test the thousands of items of evidence. In 2002, the FBI formed the Scientific Working Group on Microbial Genetics and Forensics (SWGMEG) to create quality assurance guidelines for microbial forensics and identify gaps and direction to develop a robust microbial forensics capability Budowle, 2003; Budowle et al., 2005a. SWGMEG has since disbanded; however, the recommendations laid out by the working group are still valid and very much applicable today.

Figure 1 General schematic approach to epidemiological and microbial forensic investigations.

Detection, Characterization, and Emerging Technologies

Traditional Detection Methods and Genetic Typing

Attribution is the primary goal in microbial forensics by comparison of data obtained from evidentiary samples to reference samples. Both biological and non-biological signatures can be sought for attribution, investigative leads, or exclusionary purposes. Microbial forensic evidence may reside in a wide range of samples matrices, including food, water, air filters, swab and swipes, soil, animal tissue, and clinical samples (e.g., tissue, sputum, blood, stool, urine). Therefore, an analyst must have a variety of sample processing methods available to address the demands of myriad possible samples and scenarios, and methods need to be as robust as possible. In addition, traditional forensic evidence, such as fingerprints, human or animal DNA, and fibers and hair can be analyzed. So the analyst must consider collecting and analyzing evidence in a manner that preserves other forms of evidence beyond those of the purview of microbial forensics.

Detection methods in the microbial forensic workflow can range from culture, microscopy, immunoassays, mass spectrometry, real-time PCR, microarray, genetic typing, whole-genome sequencing, and beyond. While the focus of this chapter is on genetic signatures for biological threat agent identification, non-biological signatures, such as those that infer the culture method used, manufacturing processes, time of production, and methods of dissemination can be quite informative for developing investigative leads [Velsko, 2011](#). For example, non-biological signatures pertaining to silica, growth media, and purity indicated that the anthrax spores in the 2001 attack were not weaponized in a sophisticated manner and likely were cultured from at least two batches, providing investigative value [National Research Council, 2011](#). In addition, biological evidence other than genetic signatures of threat agents, such as host immune response, can provide invaluable information for investigative leads regarding if a suspected perpetrator took prophylactic antibiotics or other antidotal substances, inferring the handling, manufacture, or possession of a biothreat agent [Schutzer, 2011](#). Culture is still considered the gold standard for pathogen detection [Peters et al., 2004](#). However, culturing cannot provide resolution, many times beyond the genus or species level, and because there can be a substantial lag time due to growth requirements of the microorganism, it may not be efficient for response especially when the safety of individuals is an immediate concern. Moreover, about 99% of microorganisms cannot be cultured by current methods; therefore culturing is not a reliable method for fastidious and possibly novel/uncharacterized microorganisms. In addition, the microbes may have been

exposed to environmental insults and may no longer be viable. So even if the microorganism was one of the few that could be cultured, no information would be obtained if it were nonviable.

Ideally, attribution seeks characterization of biological threat agents with resolution at the strain/isolate level. While culture and immunoassays are sufficient methods for initial testing and sample screening, nucleic acid typing often is more resolving. MLVA (multi-locus variable number tandem repeat (VNTR) analysis) analyzes polymorphisms found in minisatellite regions within bacterial genomes and has been shown to be effective at discriminating among strains of highly monomorphic species, such as *B. anthracis* Keim et al., 2000; Keim et al., 2004 and *Yersinia pestis* Klevytska et al., 2001; Pourcel et al., 2004. MLVA was the method used to identify the Sterne strain used in the Aum Shinrikyo Anthrax release Keim et al., 2001 and the Ames strain used in the Amerithrax attack Keim et al., 2011. This level of characterization, although not sufficient for individualization of isolates obtained from evidence, did provide a good investigative lead, as the Ames strain is not typically found in nature and is far more prevalent as a laboratory strain Keim et al., 2004; Keim et al., 2011. Since these genetic markers cannot resolve at the isolate level, SNPs (single nucleotide polymorphisms) and other genetic signatures are sought for better attribution. One approach for SNP marker detection is use of microarrays, which consist of potentially large numbers of short oligonucleotide probes on a solid support. Microarrays, which can be highly efficient screening and characterization tools, have been developed specifically for bacterial and viral detection, and can achieve species to strain level identification Gardner et al., 2010; Leski et al., 2009. However, at the isolate level the variant sites, if they exist, on the genome are unknown and may not be detected with an *a priori* array design. An unbiased more comprehensive genome scanning method is needed to extract the most resolving information possible.

Whole-genome shotgun sequencing (WGSS) is one approach that may be able to identify those species/strain/isolate markers that would enable better attribution. WGSS is a sequencing approach which does not require any prior knowledge of the sequence being determined. Because WGSS is unbiased in its identification of markers, it can provide the capability to detect any number of genetic markers, such as SNPs, insertions, deletions, duplications, genome rearrangement, virulence genes, pathogenicity islands, plasmids, horizontally transferred elements, and evidence of genetic engineering. Initially, WGSS was performed using Sanger sequencing Sanger et al., 1977. This approach requires the use of cloning vectors, has relatively low-throughput, is time consuming and rather expensive. WGSS was performed to attempt to characterize different isolates of the Ames strain including an isolate from the first known victim of the 2001 anthrax attack Read et al., 2002; however no genetic differences were observed between the evidence and reference samples. It was not until the astute discovery of late-forming spore morphology variants by a microbiologist that a potential distinguishing characteristic could be exploited for attribution purposes Keim et al., 2011. Pure cultures of some of the morphology variants were prepared and sequenced enabling detection of genetic variants specific to each morphology variant Keim et al., 2011. Sequencing many samples was cost-prohibitive as it cost on average approximately \$140,000 to perform WGSS on a single sample in 2002 Cummings & Relman, 2002. Therefore, based on genetic data from a limited number of sequenced samples, real-time PCR assays were developed to detect these different genetic signatures of the variants Keim et al., 2011. These PCR-based assays, being easier to perform and far less costly, were used to screen over a thousand (N=1077) repository samples collected from laboratories inside and outside the US housing the Ames strain Keim et al., 2011. The results eliminated the vast majority of Ames samples collected and strongly indicated an association to a flask containing *B. anthracis*, known as RMR1029, at the USAMRIID (United States Army Medical Research Institute for Infectious Diseases) Keim et al., 2011; National Research Council, 2011. This flask contained a mixture of the same colony morphology variants as was seen in the Amerithrax evidence Keim et al., 2011; National Research Council, 2011. While real-time PCR enabled analysis of a large number of evidentiary samples, the approach was limited to only the few variants that the assay was designed to detect. Therefore, any other variants that may have existed within the approximately 5 million bases of the *B. anthracis* genome would go undetected with such a focused assay. This inability to scan the entire genome in a single assay was a limitation of the technology just a decade ago. Today, identifying genetic signatures and typing a large number of samples are more feasible with next-generation sequencing technologies.

Massively Parallel Sequencing

One of the most significant genetic typing tools to come to fruition in the last few years is high-throughput sequencing. Next-generation sequencing, or better described as massively parallel sequencing (MPS), has become a mainstream technology in many molecular biology and genetics laboratories. MPS allows for the generation of gigabases of sequence data in days at a substantially reduced cost than even a few years ago Wetterstrand, 2014. Larger genomes can be fully sequenced in a couple weeks and small genomes, such as a bacterial genome, can be fully sequenced within a few days. MPS provides greater coverage across a genome with higher depth of coverage at each site for increased confidence in base calls, and barcoding allows for multiplexing of samples (from a few to hundreds) in a single sequencing run. With the introduction of smaller, faster, and cheaper benchtop sequencers, the technology now makes it feasible for the capabilities of large genome centers to be transferred to the application-oriented laboratory. Thus, microbial forensic analyses are being driven in a new direction with the new capabilities provided by MPS. Full characterization of bacterial or viral genomes can be achieved in a number of days as compared with more limited traditional methods, such as culturing, MLST (multi-locus sequencing typing) and PFGE (pulsed-field gel electrophoresis), which can take several days to weeks depending on the microorganism. Most importantly, far more genetic information can be realized and thus attribution to a deep level may become a reality for a number of scenarios. In essence, MPS provides a high-throughput, culture-independent method for whole-genome sequencing and comparative genomic analyses.

MPS was first introduced in 2005 by 454 Life Sciences based on pyrosequencing technology Margulies et al., 2005. In the past decade, the MPS possibilities have exploded and a number of novel platforms have been introduced, such as: GS FLX+ and GS

Junior (454 Life Sciences, Roche, Branford, CT); HiSeq, NextSeq500 and MiSeq (Illumina, San Diego, CA); SOLiD® 5500 (Life Technologies, Foster City, CA); Ion Torrent's Proton and PGM (Personal Genome Machine) (Life Technologies). Each system employs a different sequencing chemistry, but all provide higher throughput at a reduced cost per base pair compared to traditional Sanger sequencing. The next generation of sequencing systems, from Pacific Biosciences (PacBio) Eid et al., 2009 and Oxford Nanopore Technologies (2012), focus on single-molecule sequencing strategies. These sequencing technologies hold great potential for microbial forensics with the ability to generate long sequence reads. For example, PacBio sequencing can produce greater than 30,000 bp reads Pacific Biosciences, 2014. Also, PacBio sequencing allows for the detection of specific base-pair modifications, such as methylation patterns, that can be used for further characterization of samples Flusberg et al., 2010. Single molecule analyses may offer the important features of increased sensitivity of detection and higher quality genome assembly provided by the increased read lengths.

MPS is being fully exploited by clinical microbiology labs Didelot et al., 2012; Köser et al., 2012a and offers several different applications for microbial forensics Budowle et al., 2013. Cummings et al. (2010) evaluated MPS as a microbial forensic and epidemiological tool to detect SNP and other genetic variants within the monomorphic select agents, *B. anthracis* and *Y. pestis*. They were able to detect genomic variants and differentiate among four different strains of *B. anthracis* and four strains of *Y. pestis* simultaneously within a single sequencing run Cummings et al., 2010. This study demonstrated the ability to detect low-level variants within a sample, in particular if known genetic variant regions were amplified by PCR and sequenced in parallel Cummings et al., 2010. For example, four 200 bp genetic variants amplified by PCR would result in 800 bp total length. Cummings et al. (2010) calculated that sequencing these samples on the SOLiD® system, with a 10GB throughput (the throughput available in 2010), would result in a yield of 12.5 million read coverage; if 256 samples were multiplexed read coverage would yield approximately 50,000× and would allow for minor variant detection of less than 1 in 10,000 within a mixed sample. Today, the highest throughput available with MPS, provided by the Illumina HiSeq, is around 1TB of sequence data on a dual flow cell run Illumina, 2014. Using the HiSeq, multiplexing the same 256 samples, would result in, on average, approximately 5 million read coverage. Obviously this level of coverage is not needed for variant detection, but it demonstrates the immense amount of data that can be obtained for potential low-variant detection and the degree of sample multiplexing that is possible. The length and number of genetic targets can be increased; for example, 256 samples at a desired 50,000× coverage on the HiSeq could be used to sequence about 78,000 base pairs per sample. Therefore, this technology has the capability to dramatically reduce the number of false negatives (particularly with low level or trace analyses).

Disease outbreak investigations are integral to clinical, epidemiological, and microbial forensic investigations. MPS has been used to investigate disease and food-borne illness outbreaks, such as the 2006–08 outbreak of *Mycobacterium tuberculosis* in British Columbia, CA Gardy et al., 2011 and a food-borne *Salmonella enterica* outbreak in 2009–10 spanning 44 states in the United States Lienau et al., 2011. While these investigations using MPS were retrospective, MPS has been used to detect and monitor disease outbreaks in near real-time, such as the 2010 Haitian Cholera outbreak Chin et al., 2011 and most notably the 2011 *Escherichia coli* O104:H4 outbreak in Europe Grad et al., 2012; Mellmann et al., 2011. From May–July 2011 an outbreak of *E. coli* O104:H4 occurred due to contaminated alfalfa sprouts in Germany and France, which ultimately led to over 4000 infections and 50 deaths Grad et al., 2012. During the outbreak MPS was employed, using the Ion Torrent PGM and supplemented using Optical Mapping technology, to produce a draft whole genome sequence assembly of the outbreak strain within 62 h, Mellmann et al., 2011 demonstrating the utility of MPS as a real-time epidemiological tool. MPS has been used on a more local level as a diagnostic tool for infections Hasman et al., 2014, including mixed infections Eyre et al., 2013, and to monitor nosocomial outbreaks within hospital units Eyre et al., 2012; Köser et al., 2012b. In addition, MPS has been used to monitor patient treatment therapies, such as in the case of stool substitute implantation as a treatment regimen for recurrent *Clostridium difficile* infections Budowle, 2013. Harris et al. (2012) demonstrated that the use of MPS provides far more genetic information regarding recombination in *Chlamydia trachomatis*, than current clinical typing methods. Thus, MPS provides substantial utility for clinical diagnostics and outbreak surveillance with increased coverage of more informative genetic regions for more accurate analysis than using certain current clinical typing methods. While these aforementioned studies focus on MPS applications for mainly clinical and epidemiological uses, these same methods and practices can be applied to a microbial forensics investigation (i.e., if these same outbreaks were intentional these sample methods could be employed) and can serve as retrospective studies to facilitate interpretation of results if an attack were to occur.

MPS technologies continue to improve at an exceedingly fast rate. DNA input requirements and run times are decreasing, while multiplexing capabilities and read lengths are increasing. MPS likely will become more sensitive and have higher throughput, which will make the technology applicable to more microbial forensic applications. In addition, new methods and technologies will provide novel microbial forensic investigation applications, such as metagenomics analyses and sample preparation enrichment strategies.

Metagenomics

Metagenomics, the application of sequencing DNA collected directly from environmental and other complex community samples, provides a culture-independent method for studying microorganisms from environments such as soil Mocali & Benedetti, 2010, water Biers et al., 2009, and human-associated samples Human Microbiome Project Consortium, 2012a; Human Microbiome Project Consortium, 2012b. There is an estimated 10^{30} bacteria on earth and the majority of these species cannot be cultured Sleator et al., 2008. Thus, metagenomics applications using MPS provide tools to sequence, in theory, all nucleic acids present in a given

environmental sample, most of which could not be detected using culture-dependent approaches. New capabilities are provided for microbial community profiling, novel microbial species and metabolic pathway discovery, and microbial-host interactions for applications in areas such as environmental and clinical microbiology. Several studies have demonstrated the applicability of metagenomic sample analyses for forensic investigations such as for human identification Fierer et al., 2010; Lazarevic et al., 2010; Mason et al., 2013, cause of death Kakizaki et al., 2012; Thèves et al., 2011, time since death Hyde et al., 2013; Pechal et al., 2014, biological fluid identification and characterization Benschop et al., 2012; Brenig et al., 2010; Giampaoli et al., 2012, disease outbreak investigations Loman et al., 2013, herbal supplement authenticity Coghlan et al., 2012 (non-microbial), biogeography of humans Yatsunenko et al., 2012 and environmental samples Heath & Saunders, 2006, and public bio-surveillance Robertson et al., 2013. In addition to targeted pathogen detection from samples for epidemiological and biodefense purposes, metagenomic analyses of whole microbial community profiling hold promise for microbial forensic utility.

The types and conditions of samples that may be encountered in a microbial forensic investigation are variable and many will be mixed with other microbes and/or background eukaryotic nucleic acid and at low abundance or trace levels in a sample, making detection of, for example, select agents very challenging. Microbial forensics typically focuses on the detection and comparative analyses of priority pathogens and select agents, and more readily from relatively pure or homogeneous samples. However, forensic metagenomics detects target microorganisms in complex samples. There are currently two main approaches for metagenomic sequencing, targeting the 16S rRNA gene or WGSS. The former provides better depth of coverage but tends to lack species-level resolution, which is imperative for microbial forensics purposes. The latter can provide species or even sub-species level identification but lacks the depth of coverage provided by targeted amplicon sequencing, which limits the sensitivity of detection of target microbes. However, WGSS is more desirable for microbial forensic metagenomics analysis as species level resolution is imperative. It would not be helpful to identify at the genus level that a sample contains, for example, Bacilli. There are many Bacilli species that are not harmful and some are even beneficial. Without more information on whether a harmful species is present, no action could be taken regarding health and safety, whether an investigation should proceed, or whether a response is warranted.

Bioinformatics is the application of computational methods to analyze biological data, such as MPS sequence data and is essential for interpreting MPS sequence data, phylogenetic reconstruction, statistical analyses, and visual representation of data. With the explosion of MPS and the onslaught of sequence data numerous bioinformatics software tools and data management systems have been developed such as software tools for metagenomic assembly Namiki et al., 2012, taxonomic classification Davenport et al., 2012; Huson et al., 2007; Segata et al., 2012, phylogenetic analysis Darling et al., 2014, entire metagenomic analysis pipelines Treangen et al., 2013, and database analysis and management systems Markowitz et al., 2012; Meyer et al., 2008; Sun et al., 2011. Software that use sequences specifically informative for species or sub-species level identification from shotgun sequencing data, such as Pathoscope Francis et al., 2013 and SIANN Minot et al., 2014 will allow better attribution. These programs were developed for species- and strain-level detection of pathogens or other target microorganisms from shotgun sequencing data with direct application for clinical diagnostics and/or microbial forensics. Customized bioinformatics tools and comprehensive databases for microbial forensic purposes are essential.

New Tools from Paleopathology Investigations

Ancient microbial analyses are another branch of forensic related efforts that expand the limits of analyzing challenged samples. Throughout history disease outbreaks have led to the deaths of millions of people throughout the world. For example, the Spanish Influenza pandemic killed more than 50 million people Johnson & Mueller, 2002, and multiple plague epidemics have afflicted different regions of the world throughout history leading to the deaths of significant portions of the human population in these areas, sometimes as high as 50% of the population Holmes, 2011. For some of these epidemics the underlying cause or causative microorganism is known; for some historical events, the causative agent remained a mystery or was controversial. New and improved extraction methods, more sensitive detection assays, and new sequencing technologies have been developed enhancing the capability to genetically characterize these ancient pathogens from skeletal remains and other sample types. These studies contribute new representative genomes to fill in missing diversity from the phylogenetic tree, thus aiding in the epidemiology of modern outbreaks of these same species.

Y. pestis, the causative agent of plague, remains an important health focus. Plague has been responsible for several of the most devastating pandemics, specifically the Justinian Plague, the Black Death, and the twentieth century pandemic Morelli et al., 2010. Therefore, knowledge of the causative strains from these outbreaks and reconstructing phylogenetic relationships with new and old strains can be used for modern outbreak investigations Yan et al., 2014. Recently researchers have utilized novel enrichment strategies coupled with MPS to extract and reconstruct the draft genomes of *Y. pestis* from victims of the Black Death Bos et al., 2011; Schuenemann et al., 2011 and the Justinian Plague Wagner et al., 2014. Due to the highly fragmented and damaged properties of ancient DNA, novel library prep methods and enrichment strategies using baits comprised of complementary nucleic acid sequences were used Bos et al., 2011; Schuenemann et al., 2011; Wagner et al., 2014. Enrichment strategies employed the use of probes, constructed from modern reference sequences, which are suspected to be highly similar to the ancient sequence, with biotin tags attached to streptavidin coated magnetic beads or probes attached to glass slides to retrieve target endogenous DNA. These same enrichment approaches could be used in more modern microbial forensic samples to capture sequences of interest (i.e., sequences from a biothreat) from highly complex samples, providing a new microbial forensic tool for metagenomic analyses. The historical epidemiology of other priority pathogens are of interest as well; a historic strain of *M. tuberculosis*, the bacterium which causes tuberculosis, was isolated and genotyped using enrichment strategies coupled with SOLiD® sequencing from nineteenth century

skeletal remains [Bouwman et al., 2012](#). These studies demonstrate the capability to detect priority pathogens and select agents from highly degraded samples, which may be important in certain microbial forensic investigations.

Synthetic Biology

As molecular technologies advance, new tools will arise that benefit society and at the same time be exploited for criminal purposes. Synthetic biology, the ability to synthesize any genomic sequence both naturally occurring and artificial, is one such dual purpose technology. The ability to synthesize DNA of any sequence, transform bacteria and viruses with selected genes, recreate known but difficult to attain pathogens (including extinct ancient pathogens), and even create novel microbial genomes is a growing reality. Although most biosynthetic efforts concentrate on, for example, studying genes, altering cell lines to study diseases, generating therapeutic solutions, and bioenergy [Khalil & Collins, 2010](#), this same biosynthetic capability could be used to generate a microorganism to use as a biological weapon or could create unintentional consequences of an accidental release. Pathogenic microorganisms and toxins naturally occurring in hosts and the environment will continue to be a main biothreat. However, it is reasonable to consider the threat of creating difficult to obtain microbes that reside in unknown reservoirs, such as Ebola, secured microbes, such as smallpox, or microbes no longer in nature, such as the Spanish influenza H1N1 virus [Bügl et al., 2007](#); [Tumpey et al., 2005](#). [Bügl et al. \(2007\)](#) have highlighted the significance of this capability and the need for a structured framework for DNA synthesis and biological security.

Regulations are in place regarding the creation of genomic sequences of select agents [National Select Agent Registry, 2014](#), and recommendations have been made, for example, by the National Science Advisory Board for Biosecurity, regarding the need to block publication of reporting findings of infectious agents that could be used to cause harm by malicious persons or groups [Berns et al., 2012](#). Recommendations need to be in place regarding the safety and biocontainment of synthetically created microorganisms, as an accidental release could cause just as much harm as an intentional release. Microbial forensic methods using MPS can be used to monitor and detect synthetically created microorganisms. Since MPS is not biased regarding marker or signature analyses, it can be used to determine if a gene(s) or plasmid(s) is inconsistent with the previously known microorganism genetic background, suggesting a deliberate attempt or success of synthetically creating a biothreat.

Interpretation of Microbial Forensic Results

Proper interpretation of microbial forensic evidence is imperative for establishing confidence, to withstand the scrutiny of the legal system and for making critical policy or response decisions. Microbial forensics, much like human forensic DNA interpretation, can support the conviction or exoneration of an individual. However, more dire consequences can occur or be prevented based in part on a microbial forensic result. In the case of a bioterror attack, attribution to a particular government or sovereign entity could result in diminished diplomatic relations or military retaliation. Therefore, proper guidelines, validations and quality assurance, and statistical support need to be in place for microbial forensic evidence interpretation. Microbial forensic analyses typically rely on the comparison of evidentiary samples to a known reference sample(s) or other evidentiary item. The three general types of interpretation, include: inclusion; exclusion; or inconclusive. An inclusion, or association, is stated when the evidentiary profile matches, or is highly similar, to the comparative profile. In microbial forensics an inclusion also can mean that the microorganism from the evidentiary sample and comparative microorganism share a recent common ancestor. An exclusion is stated when the profiles are sufficiently dissimilar such that they cannot have originated from the same common ancestor or from the same source. An inconclusive is stated when there is insufficient information to render an interpretation. When an interpretation of an association is made, a statistical assessment or weight is assigned to this interpretation. These results are combined with other metadata to determine whether there is support, for example, of an intentional attack and that a particular person or persons are the perpetrator.

When associations are made between an evidence and reference sample the significance of the weight of the results must be properly stated. Currently there are no standard interpretation guidelines for microbial forensic evidence. However, some recommendations have been made. Although standard interpretation guidelines are lacking in the microbial forensics field, phylogenetic analyses have supported associations and have successfully been admitted as evidence in legal criminal proceedings in the United States and abroad [Bhattacharya, 2014](#). Reconstructing phylogenies has been used as a microbial forensic tool to convict individuals in cases of intentional infection with RNA viruses [González-Candelas et al., 2013](#); [Metzker et al., 2002](#); [Sajantila, 2014](#); [Scaduto et al., 2010](#). A well-known case in which phylogenetic analyses supported an investigation in a criminal matter was in the second-degree attempted murder case in which Dr. Richard J. Schmidt was accused of intentionally injecting his girlfriend, Janice Trahan, with HIV [Metzker et al., 2002](#). On August 4, 1994, Dr. Schmidt allegedly injected his girlfriend with a mixture of HIV and hepatitis C virus (HCV) tainted blood from two of his patients [Metzker et al., 2002](#). Subsequently, Janice Trahan was diagnosed with HIV [Metzker et al., 2002](#). An investigation occurred and sequence data of two genes (*gp120* and *RT*) were generated from samples from the HIV-positive patient, Janice Trahan, and a local population of HIV-positive patients (about 30 control samples and 2 database samples) [Metzker et al., 2002](#). Phylogenetic analyses revealed that the HIV variants between the patient and the victim were more similar than those from the local population [Metzker et al., 2002](#). This evidence was used in the conviction of Dr. Schmidt [Metzker et al., 2002](#). Phylogenetic analysis also was used in the investigation and submitted as evidence in the case of a Spanish anesthetist, Juan Maeso, who allegedly infected 275 of his patients with HCV by injecting himself with some of the patients' morphine prior to

administering the drug to patients using the same needle [Bhattacharya, 2014](#); [González-Candelas et al., 2013](#). In February 1998, an HCV outbreak was investigated and led to the association of hundreds of cases linked to two hospitals where Maeso worked [González-Candelas et al., 2013](#). Sequence data were generated from two genes (NS5B and E1-E2) from 322 patients and 44 local controls [González-Candelas et al., 2013](#). These data led to the exclusion of 47 patients from the outbreak strain and association of 275 patients infected by Maeso [González-Candelas et al., 2013](#). Maeso was convicted of professional malpractice [González-Candelas et al., 2013](#). This case differed from other cases using phylogenetic analysis since this case spanned a longer time frame, nearly 25 years, and involved many victims; as such, a molecular clock analysis was used to infer the time of infection of some of the patients [González-Candelas et al., 2013](#); [Sajantila, 2014](#). These accounts of phylogenetic analysis and use of models, such as the molecular clock analysis, will provide insight into best practices of interpretation that should be considered for assessing statistical significance.

Endemicity can play a large role in microbial forensic investigations for weighing the probability of the presence of a microorganism being due to a natural or intentional outbreak. The lack of endemic data played a key role in the difficult response of a partial positive result for *Francisella tularensis* (a NIAID Priority Pathogen and select agent) from routine sampling in the BioWatch program in Washington, DC in 2005 [Eshoo et al., 2011](#). On September 24–25, 2005 partial positive results for a low-level signal of *F. tularensis* were reported from routine air sampling in the Capital Mall area of Washington, DC [Eshoo et al., 2011](#). This detection occurred during the time of an antiwar protest, attended by a large number of people [Eshoo et al., 2011](#). *F. tularensis*, a highly infectious bacterium, is a naturally occurring microorganism endemic to many areas and has been found in samples such as air, water, and soil [Barns et al., 2005](#); [Kuske et al., 2006](#). Shortly after the partial positive result, the CDC issued a health advisory to inform public health officials and individuals of potential exposure; however, no infections were reported [Eshoo et al., 2011](#). It is more likely that the large movements of the protestors stirred up natural dust and excrement from the ground that contained endemic *F. tularensis* as opposed to the result of an intentional bioattack.

Endemic data assist in source tracing of microorganisms and to trace the origin of a particular microorganism, especially in the case of a disease outbreak. In 2010 following the Haitian earthquake, there was an outbreak of cholera, a disease caused by the bacterium *Vibrio cholerae*, resulting in more than 470,000 cases and more than 6,600 deaths by 2011 [Centers for Disease Control and Prevention, 2011](#). Source tracing of the *V. cholerae* strain, using MPS to sequence clinical isolates, determined the origin to be a strain from South East Asia [Chin et al., 2011](#); [Hasan et al., 2012](#), specifically Nepal [Hendriksen et al., 2011](#), likely introduced by human activity such as humanitarian aid in response to the earthquake. Source tracing also can be used to investigate microbial contaminants to provide associations or indication of intentional or accidental contamination aiding in microbial forensic investigations. For example, in 2009 multiple cases of injectional anthrax were diagnosed among heroin users in Scotland [Price et al., 2012](#). *B. anthracis* is not endemic to Scotland [Price et al., 2012](#). The source of the infection was believed to be a batch of heroin [Price et al., 2012](#). Canonical SNP genotyping and WGSS were used to determine the strain and origin of the *B. anthracis* spores, which were likely introduced in Turkey or surrounding areas [Price et al., 2012](#). This source tracing method indicated likely contamination from an endemic source, possibly from using an animal-derived cutting agent and determined the likely drug trafficking route that was used to smuggle the drugs into Europe [Price et al., 2012](#).

Microbial contamination was a potential signature in the 2001 Amerithrax case. Some of the letters contained a contaminant of the bacterium *Bacillus subtilis*, a non-pathogenic near-neighbor of *B. anthracis* [National Research Council, 2011](#). Although, this contamination of *B. subtilis* did not provide any additional investigative lead value in the Amerithrax investigation, it was noted by the NAS (National Academy of Sciences) Review of the FBI's investigation that such co-cultured contaminants could be considered endemics of an area or of a laboratory and could be invaluable evidence in future cases [National Research Council, 2011](#), to trace the origin of the biothreat producer or to trace routes of dissemination. Knowing the types of strains and the geographic areas they reside helped in determining that the Ames strain is not a common endemic in the United States and indicated a likely source would be laboratories. The Ames strain was used for research and a number of laboratories had access and housed stock cultures of this strain [Keim et al., 2011](#).

Databases are an essential tool in microbial forensics. Microbial forensic interpretations require the comparison of evidentiary genetic data to fully characterized references comprised in databases. Databases must be as inclusive as possible and contain as many strains of a particular species as possible, in addition to near-neighbors and other microorganisms representative of a wide range of phylogenetic diversity. Population genetic data within databases can be analyzed to provide information for unique markers for genetic typing for assay development and other data such as mutation rates and diversity. In addition to genetic data, databases must contain associated metadata. Metadata are the information associated with a given sample such as collection site location, date of collection, tissue source, virulence, extraction and sequencing methods, assembly and annotation methods, etc., which can be used to determine endemicity and other information associated with quality control of data. Metadata are essential to epidemiological investigations providing information to aid in source tracing and therapeutics and essential to microbial forensic investigations providing invaluable supplementary information of investigative value.

Since the majority of microbial diversity is unknown, current databases may not represent the true range of diversity that exists and programs have been initiated to sequence more reference genomes [Wu et al., 2009](#). However, in microbial forensics the focus is on microbes that are particularly infectious and/or pathogenic and many representatives have been sequenced and with continued improvements in MPS, the number of microbial genomes that will be available will also increase. For example, the HMP (Human Microbiome Project) Consortium initiated the task to sequence new reference genomes for enhancing interpretation of health vs disease-state microbiomes [Human Microbiome Jumpstart Reference Strains Consortium, 2010](#), and the 100K Foodborne Pathogen Genome Project seeks to sequence 100,000 different food-borne pathogens to help with epidemiological investigations [UC Davis](#)

School of Veterinary Medicine, 2014. More inclusive databases with reference sequences of forensic relevance can help improve source tracing efforts and phylogenetic reconstructions to determine disease transmission in biocrime and other biothreat cases. Databases constructed for biosecurity purposes must be systematically curated, have high quality genome sequences and the number and quality of draft genomes included must be properly vetted. Recommendations and guidelines also must be in place for metadata, including security-related regulations Sjödin et al., 2013. International databases would improve the capability of determining strain level attribution and source tracking Yang & Keim, 2012; however, international databases likely will not come to fruition as it requires countries to share information that they may regard part of their own national security or may not want to release as outbreaks can have serious economic consequences.

Conclusion

Microbial forensics is an interdisciplinary field that involves scientists, public health, law enforcement, the intelligence community, and policy and decision makers. Together they provide the interconnected system that helps protect us from naturally occurring disease outbreaks and acts of biological terrorism and biocrime. New advancements in molecular techniques, especially sequencing technologies, provide tools for the microbial forensic scientist to extract more information at dramatically reduced costs and faster turnaround times than previously possible. It is imperative for researchers in the field to continue to pursue novel research in areas such as method and software development and comparative genomics, as well as further expand our virtual and physical databases and biospositories. Continuous evaluation and updates to quality assurance and quality control practices should be maintained to uphold microbial forensics practices to the highest of standards. Interpretation of results in a microbial forensics investigation must meet rigorous criteria and proper validation. It is important to understand the limitations of a method so as not to overstate results especially in the cases of exigent circumstances during an imposing threat. New genomic technologies and data, inclusive databases with expanded reference genomes, extensive endemic data, and validated methods all contribute to the proper interpretation of results in a microbial forensic investigation. High quality and confidence of results are essential since microbial forensic interpretations can have a large impact on society, regarding safety, political policy, and economics. Challenges will continue to exist in microbial forensics, however, implementation of new technology and continued communication across the scientific, public health, law enforcement, intelligence and policy communities will contribute towards the advancement of the microbial forensics field.

Microbial Mats: Impact on Geology

Geobiology: An Evolving Discipline

Emphasis on interactions across traditional discipline boundaries rather than on the core disciplines lead that *Geobiology* is mostly concerned with exploring the interface and complex relationships between the biosphere and geosphere. This subject was discussed in a colloquium convened by the American Academy of Microbiology, held in 2000 in Arizona, where the interconnecting fields of biological and geological sciences was considered. Despite the living extent may seem to be unconnected from nonliving, these two realms form a single prolific domain. Geological and biological activities influence each other in intense ways. This interaction has formed the Earth and all organisms on it. In that sense, Neelson et al. (2001) described this interaction as a Geobiological Tango: *"Living creatures and the inanimate worlds they inhabit dance an intimate tango. As each partner steps to Nature's tune, the other responds in harmony... This interplay of Life with Earth has shaped our present environment."* Life evolved from chemicals and their activities modified the environment. In case, the gases we breathe have been created by geobiological interactions. So, the interaction at all scales in space and time is under the umbrella of this modern and fast evolving discipline.

Geobiology has recently been defined by Knoll et al. (2012) as the scientific discipline in which the principles and tools of biology are applied to studies of the Earth. How life began, how it evolved, and how environmental conditions have influenced these processes are studied by geobiologists. Therefore this discipline produces new discoveries that contribute to a better comprehension of Earth in modern and past times. Moreover, the search of life beyond the Earth (i.e., astrobiology) is extending and, in that sense, geobiological approaches provide the basis for studies that focus on the exploration for extraterrestrial life on other planets (Baumgartner et al., 2009; Cady and Noffke, 2009, and references there-in).

Since the past few years, several studies are concerned in knowing the ways in which the organisms affect the Earth and the interactions between biological and physical processes in order to infer their participation in the planet's history. This interaction is useful for geologists in the interpretation of ancient sedimentary rocks, which requires the comprehension of processes resulting in a particular sedimentary stratum. A major bridge that joins the past with the present is the world of microbiota, such as cyanobacteria, the only oxygenic phototrophs known to have existed from before 2 Ga up to the present (Knoll et al., 2012). When plants and animals evolved and, due to a rapid growth of grazing metazoan communities extensive microbial mats became scarce (Grotzinger, 1990). However, they are still present in many ecosystems and have a significant impact on global biogeochemical cycles. Today, extensive microbial mats only exist in special places where they have little competition from vascular plants or grazing animals (Pflüger and Gresse, 1996). From a geological point of view, the interaction of organisms with their depositional environment is very important, because this interaction defines distinctive and preservable sedimentary signatures, giving a clear evidence for biological activities. A very useful proxy is the study of processes on modern settings as analogues of ancient environments. Although the processes are similar (not identical), they often provide useful hypotheses for the interpretation of the processes that occurred in the past.

From Biofilms to Microbial Mats

In most shallow-marine environments, sediments are densely populated by benthic microorganisms as pennate diatoms that form biofilms around individual sediment grains as an initial step. Then, continuing to its expansion to adjacent grains ultimately can form a laterally continuous organic layer (Fig. 1). Biofilms, thin cohesive microbial communities, and well adapted benthic consortia, in favorable nutrient-enriched conditions develop complex, multilayered microbial ecosystems called microbial mats (Castenholz, 2009). The benthic microbial communities are commonly dominated by photosynthetic prokaryotes, mainly cyanobacteria and other photosynthetic bacteria, and also by eukaryotic microalgae, such as epipellic diatoms. This microphyto-benthos colonizes sediments in shallow marine or estuarine settings, forming biofilms or microbial mats. They are common in salt marshes and estuaries (Fig. 2(A)) that may extend their distribution even into the lower intertidal zone (Stal, 2010). However, they may also be found in peritidal environments, such as coastal lagoons (Javor and Castenholz, 1981), as well as in extreme environments with high temperatures and hypersaline conditions.

The formation of a microbial mat comprises the secretion of an exopolymer to allow the microorganism to adhere to the substratum (Decho, 2000). Sediments are commonly embedded in this thick mucilaginous matrix of extracellular polymeric substances (EPSs), which may consist of 90% or more of polysaccharides, forming sticky coatings on individual sediment particles (Fig. 2(B) and (C)). EPS aid in the organisms vertical migration in response to light and tidal conditions, and in turn this substance also bind sediment particles together and they can form a smooth layer on the sediment surface (Fig. 2(D)). Thus the sediment bed is highly influenced by EPS affecting their stability (Paterson, 1989, 1997). So, the movement of filamentous microorganisms between the sediment grains forms a dense, mesh-like meshwork (see Fig. 1(C)). Moreover, due to the presence of EPS, microbial

This article is a reprint of Diana G. Cuadrado, Microbial Mats: Impact on Geology, *Reference Module in Life Sciences*, Elsevier, 2017.

Fig. 1 Colonized sediments in Bahia Blanca Estuary tidal flat. (A) Extensive microbial biofilm as a protection of the substrate. Erosion of thin biofilm shows different colored sediment underneath (pointed by black arrows). Gas domes are formed (pointed by white arrows) by uprising gases of buried decaying organic matter and photosynthetic activity of microorganisms. (B) A footstep over a thin biofilm made by gliding over slippery fine sediment below resembling a waving cloth (white arrows) forming wrinkles (red arrows) on the biofilm. This fact shows the flexibility and cohesion aspect the biofilm carpet has. There is a protuberance (black arrows) at the border of the footstep inferring soft underlying sediment.

Fig. 2 Microbial mats. (A) Filamentous cyanobacteria (green filaments) interwoven sediment particles in the uppermost surface of a plain. Below there is an anoxic black layer due to bacterial activity. (B) Sediment grains coated by extracellular polymeric substances (EPSs) as a sticking glue giving cohesion to the sediment particles. (C) Scanning electron microscope (SEM) micrographs showing the EPS between the particles as polysaccharides net. (D) Bundle of trichomes of *Microcoleus chthonoplastes* in a common mucilaginous sheath coated by sediment particles, mainly platy-silty grains.

cells typically present a high potential for resiliency during periods of physical stress (e.g., changes in salinity and temperature, UV irradiation, desiccation, inundation) (Decho, 2000). This resiliency can also be extended to direct physical processes, such as water flow and wave activity, and where the colonized upper sediment establishing flat surface is eroded by a flow current the non-colonized sediment beneath behaves in a different manner, i.e., forming ripples (see below erosional pockets).

Complex morphological features were produced by certain microbial behavior. By virtue of gliding motility of some filamentous cyanobacteria, the formation of reticulate structures occurs, being common in natural microbial mats as well as in the fossil record. They were found in different environments, such as extreme settings (Petroff et al., 2010; Bosak et al., 2012), closed coastal lagoon (Horodyski, 1977), coastal sabkha (Gerdes et al., 2000; Taj et al., 2014), closed coastal plain, and also they were studied under laboratory experiments (Shepard and Sumner, 2010; Bosak et al., 2012). The reticulate morphology comprises polygonal and elongated bulges over a lower topography where the intersections involve vertically growing microbial filaments forming a tuft

Fig. 3 (A) Initial formation of reticulate structures by the gliding motility of cyanobacteria in a shallow pond (2 cm of water depth). (B) Reticulate structures without water in an evolutionary stage. (C) Desiccated reticulate structures with small pinnacles and tufts after several days under solar radiation. Analogous structures can be found in fossil rocks. The arrows show the border of a recolonized fold-over mat.

texture (Fig. 3(A) and (B)). Cell motility is crucial for the development of reticulates and filaments organize into reticulates faster than cell division and growth. Shepard and Sumner (2010) used the motile strain *Pseudanabaena* for their experimental studies, while Fujisawa et al. (2010) studied the vigorous gliding motility of filaments of *Arthrospira*. *Phormidium*, *Lyngbya* sp., *Microcoleus chthonoplastes* change in grow direction into a vertical position and rise above the mat forming pinnacles (Gerdes et al., 2007). Laboratory experiments stated that in the early stages of formation of microbial reticulates, at least a lamina of water is required, pointing to the importance of calm conditions for their establishment (Fig. 3(A)). This is in agreement with the general insight of calm hydrodynamic conditions needed for the formation and preservation of microbial mats. However, after the aerial exposure that gives their desiccation (Fig. 3(C)), the reticulate structures can resist hydrodynamic regimes of high energy (Cuadrado and Pan, 2017). The consolidated pinnacles and tuft we found in the field was also reported for sedimentary textures for Precambrian rocks (Tice et al., 2011).

Geochemical Processes

All trophic groups (i.e., primary producers, consumers, and decomposers) are present in microbial mats, which is of great importance from an ecological perspective. Their populations are arranged into specific communities in different layers interacting with each other and their environment (Stolz, 2000). The top sedimentary layer is formed by cyanobacteria and diatoms. They are primary producers prompting organic material using sun light by photosynthesis. Organic matter of deceased primary producers is gradually decomposed by heterotrophic microbes that are established directly beneath the cyanobacteria–diatoms layer. Deceased cyanobacteria and EPS are transformed by chemoorganotrophic bacteria forming simpler chemical compounds. These large diversity of species within microbial mats support a wide spectrum of metabolic processes (Visscher and Stolz, 2005) resulting in coupled reactions (e.g., reduction and oxidation of essential elements, such as C, S, N; or, alternatively, stepwise oxidation or reduction of a compound) that support robust biogeochemical cycles (Fig. 4(A) and (B)). The result might be the formation of gases (Fig. 4(C)) and mineral precipitates.

Carbonate and Siliciclastic Environment

In a carbonate environment, the biogeochemical processes enhance precipitation of Ca_2CO_3 from seawater causing stromatolites, a huge biogenic system that is of significant interest to geologists, microbiologists, and ocean chemists. They reach some meters in height and are mainly formed by cyanobacteria and associated heterotrophic bacteria, which developed massive microbial reefs throughout shallow waters of Precambrian oceans and provide significant information on the microbiogeochemical processes interaction during their formation and the precipitation of CaCO_3 . They are the assemblage of processes that promote the precipitation of CaCO_3 minerals, such as aragonite and calcite, and the trapping of sedimentary particles.

However, there is another sedimentary environment, the barely studied siliciclastic environment characterized by quartz sediments instead of carbonate sediments. In such siliciclastic environment, predominantly in cold waters, the chemical precipitation of minerals is less important than physical processes. Benthic microbiota colonizes the sedimentary plain and responds actively to the hydraulic movement of sediments being the microbial–physical interaction more important than biogeochemical processes (Noffke, 2010). This interaction displays a great variety of microbially induced sedimentary structures (MISSs) (after Noffke et al., 2001) that have the same significance for interpretation of Earth history as stromatolites.

Fig. 4 (A) Vertical section of microbial mat showing, mainly two layers, an oxic one above and anoxic below. The oxic layer has a very thin green layer of cyanobacteria covered by a very thin layer of diatoms to protect the underlying filamentous cyanobacteria (inset (B)). These two uppermost layers present a wavy characteristic. (C) Example of sealing of the sedimentary surface forming gas domes that inhibit the exchange of gases between sediment and atmosphere.

Mineral Precipitation

Much of the studies on mineral precipitation by the influence of microbes have been carried out in calcium carbonate minerals. This is the case of the growing of build-ups stromatolites formed essentially by two processes: (1) the microbial communities responsible for successive “trapping and binding” of sediment; and (2) in situ precipitation of calcium carbonate. The precipitation of minerals led the lithification that preserves the biosedimentary structure. Two key and intimately joined components are involved in carbonate precipitation within microbial mats: (1) the alkalinity engine and (2) the organic matrix (Dupraz et al., 2011). The alkalinity engine changes the saturation index in two manners, intrinsically and extrinsically. Intrinsic alkaline engine refers to the microbial metabolism, the way the microbial communities acquire their energy and their source of carbon. While the mechanisms those microbial mats promote the precipitation of carbonate minerals involves: oxygenic photosynthesis, aerobic and anaerobic respiration, chemolithoautotrophy; the extrinsic alkaline engine comprises mainly two physicochemical processes: water evaporation and CO₂ degassing. In both cases, the organic matrix of EPSs, which embed the microbial communities, is the physical location where carbonate minerals nucleate and grow. Cyanobacteria are considered to be the major producers of EPS. However, many other bacteria can produce EPS matrix, in case anaerobic bacteria, especially sulfate-reducing bacteria, are known to produce large amounts of EPS (Bosak and Newman, 2005; Braissant et al., 2007).

The numerous studies on carbonate environments colonized by microbial mats has demonstrated that a rapid mineral precipitation and early cementation promote a quick lithification by the precipitation of calcium carbonate, enhancing thus the preservation potential of sedimentary rocks in the form of stromatolites. Unlike, as was mentioned above, studies in the siliciclastic tidal flats revealed that the lithification would be supported by the precipitation of hydrated aluminosilicates among others. This mineral precipitation is responsible for early cementation and subsequent preservation of sedimentary structures in an area where carbonates are scarce. Cuadrado et al. (2012) documented the precipitation of microscopic authigenic zeolites, identifying trigonal trapezohedron crystals of analcime, tabular clinoptilolite, elongate rods of mordenite, radiating clusters of phillipsite and chabazite (Fig. 5). This mineralization was associated with small (micrometer scales) crystals of framboidal pyrite and magnetite, which are frequently covered by EPS remains. The EPS substances synthesized by microorganisms within the microbial mats, may have acted as mineral nucleation sites favoring the precipitation of small zeolites, like the carbonate precipitation in analogous carbonate environments. It is worthy to mention that the dominant cyanobacteria in the microbial mats were the cyanobacteria *M. chthonoplastes* forming a tough coherent mat; while the pennate diatoms 40–100 µm in size were *Nitzschia* spp., *Diploneis*

Fig. 5 Scanning electron microscope (SEM) micrographs showing the mineral precipitation in microbial mat in the Bahia Blanca Estuary. (A) In a mixed sediment and diatom assemblage, chabazite occurs as rosette-shaped crystal (arrows). (B) Halite cube crystals probably diluted by the sample preparation. (C) Clinoptilolite (pointed by arrows) with one or two sets of triangular or truncated faces on the edges. The crystals are immersed in a matrix formed by extracellular polymeric substances (EPSs) and mainly navicoid diatoms (Di). (D) Matrix and filaments of EPS where the diatoms (red arrows) and sediment particles are immersed.

spp., *Amphora* spp., as the most abundant diatoms, while $>100\ \mu\text{m}$ pennates diatoms were *Pleurosigma* spp., *Gyrosigma* spp., less frequent (Pan et al., 2013).

Although in siliciclastic environments the mechanism of mineral precipitation is poorly documented, the activity of sulfate-reducing bacteria in the mat increases the alkalinity and reduces the pH, leading to desilicification of the diatom frustules in the mats (Kremer et al., 2008). Thereby, it can be achieved two essential conditions for zeolites precipitation: alkalinity and silica, so the potential role of microorganisms and EPS cannot be ignored.

Sediment Stabilization

One of the actions associated to the sediment colonization by microbial communities is the modification and stabilization of the sediment surface. Development of microbial mats requires an environment with low sedimentation rates that enable the vertical movement of photoautotrophic microorganisms toward the surface of the sediment to obtain optimum sunlight without been buried. Microbial mats are highly organized laminated communities, where cyanobacteria are usually recognized as the most important EPS producer. One of the most extensively distributed cyanobacteria, *M. chthonoplastes*, comprises filaments constituted by several trichomes, surrounded by a mucous hyaline sheath. These sheaths consist mostly of EPS, providing a mat resistance to degradation and erosion and where the fine particles of sediments are adhere (Fig. 6(A)). Newman et al. (2017) pointed that fine grains coat the sticky sheaths of filamentous cyanobacteria as *Nodosilinea* sp. and this fact contribute the fossilization potential of cyanobacteria without the preservation of interior cells. Moreover, benthic diatoms are also important EPS producers. The EPS occurs as a matrix or linkage of strands in the interparticle voids of the sediment (de Winder et al., 1999; Fig. 6(B)). The condensed meshwork made by diatoms and interweaving microbial filaments together with mucilaginous matrix of EPS contributes significantly to increase the cohesion of the detrital grains giving resistance to erosion and resulting in biostabilization (*sensu* Paterson et al., 1994). Sometimes, cyanobacteria layer (bluish green in color) is covered by a very thin diatoms layer (light brown in color) acting as a protection from UV radiation (Fig. 7).

During low-energy phases in high tide, cyanobacteria (mainly the filamentous *M. chthonoplastes*) move up the sediment in order to reach optimal light conditions (phototaxis), orienting their filaments vertically. This action, termed “baffling” by Noffke (2010), makes slower the sediment transport and so, suspended silty sediments deposit, and mats become enriched in silt-sized particles.

Fig. 6 (A) Filament of cyanobacteria coated by platy fine sediment due to the extracellular polymeric substances (EPSs) mucilage. (B) Dense and sparse filaments of EPS coated by platy sediments that contribute to the sediment biostabilization.

Fig. 7 Microbial mat showing the cyanobacteria layer below a thin layer of diatoms in Paso Seco (Argentina). *Microcoleus chthonoplastes*, the dominant cyanobacteria in the microbial mat, lacks of scytonemin, a pigment that provides a broad absorption in the UV and violet wavelengths. Contrarily, the microorganisms that inhabit the surface contain this pigment to withstand the solar radiation.

Moreover, biomass enrichment by means of cell replication, under favorable sunlight, temperature, humidity, and available nutrients, leads the growth of the microbial mats. By the other hand, “trapping” is the action of the sticky EPS glue small-sized particles to the mat surface, while *binding* is the formation of a mat fabric during calm conditions by the active movement of cyanobacteria generating a mesh-like network.

The lower intertidal zone in temperate siliciclastic tidal flats, with a short aerial expose period, is colonized only by a biofilm. The upper intertidal zone, which gets inundated twice every day with a longer aerial exposition, a microbial mat is formed in just a few hours, being the main builder the cyanobacteria *Oscillatoria limosa*. Single trichomes interweave with sand particles in the upper mm of the sedimentary surface. In contrast, the lower supratidal zone, inundated periodically only by spring tides and sporadically during storms events, is characterized by planar microbial mats, arising from the construction of a coherent network by *M. chthonoplastes* filaments in presence of abundant EPS on top of the sedimentary surface. Both types of cyanobacteria colonization (consequently the microbial mats they form) affect the biostabilization in a different manner. Microbial mats in the intertidal zone raise the erosional current velocity due to the mesh between the sand grains and the filaments, resulting in a rough sedimentary surface. However, microbial mats in the supratidal zone raise the erosive shear strength in 9–12 times compared with uncolonized sediments due to the slippery surface by the EPS richness (Noffke, 2010). These values were overpassed by wave shear stress calculated over a similar type of microbial mats during storms (Cuadrado et al., 2013).

By another point of view, the biostabilization also enhance the preservation of footprints as was demonstrate on a study carried out over the tidal flat of the Bahía Blanca Estuary (Carmona et al., 2011), where the morphologic modifications of several bird-footprints were recorded by the course of 10 months. This study revealed that footprints showed resistance to the regular tide and wind erosion and also to the heavy rains and storms that affected the tidal flat. This resistance is clearly associated with the presence of microbial mats, which biostabilize the sediment, and where the presence of authigenic minerals may also favor the consolidation of the footprints. The morphology of the footprints is also affected by the mat thickness, the tracks were deeply imprinted and the fine details were erased in areas with thick microbial mats. Contrarily, in zones colonized with thin microbial mats overlying cohesive mud, the traces preserved details, such as skin impressions and slipping marks (Fig. 8). Probably, this might be the way the delicate fossil impressions are preserved.

Microbially Sedimentary Structures

Due to the interaction of benthic microbiota with sediments, microbially sedimentary structures are formed and they are influence by the environment dynamics. The studies in modern settings allow inferring analogous process in the fossil record because sedimentary structures are preserved along great part of the Earth history. Eriksson et al. (2007) modified a previous scheme (Schieber et al., 2004) inferring genetic processes subject to microbial influences during deposition or diagenesis as the responsible for the sedimentary structures. The structures classification scheme they presented in geology is related to biostabilization, especially to mat grow, mat metabolism, mat destruction, decay and diagenesis for both, sandstone and mudstone. Therefore the detailed knowledge of the processes involved in the modern microbial mat colonization of sedimentary substrate is an essential tool for the correct geological interpretation of the paleoenvironment that led to such sedimentary deposits.

The fossil microbial structures found in the sedimentary rocks are consequence of taphonomic windows (Noffke, 2010). Two taphonomic stages are involved: the preservation processes that occur immediately at the time of the sediment deposition (primary process or syndepositional), and the preservation processes that occur after burial of sediment (secondary or postdepositional). Where the ecological and taphonomic windows overlap, the microbially sedimentary structures occur.

Fig. 8 Shorebird footprints over thin microbial mats showing delicate skin impressions. Due to biofilm formation the footprint details may be preserved in a sedimentary rock as fossil impression.

Different MISS were found in the modern environment and respond to particular process. In Bahia Blanca Estuary is common to find shrinkage cracks, mat domes, flipped-over mats, microbial chips, erosional pockets, and remnants (Cuadrado et al., 2012), as a consequence of estuarine process (Fig. 9). Shrinkage cracks constitute mat-destruction structures formed due to subaerial exposure and desiccation of the mats, typical of supratidal areas, where the upper surface of the mat undergoes greater contraction than the underlying layers (Fig. 9(A)). Typically, open cracks are favorable sites for the new growth of microbes, so when the surface gets wet again mat cracks are overgrown by the newly formed microbial mats and “healed” (Fig. 9(B)). Gas domes occur when gases trapped beneath the relatively impermeable microbial film accumulate, increasing the pressure and pushing the mat upward, producing a bulge and a hollow cavern underneath (Fig. 9(C)–(E)). Its formation requires gas production underneath or within the mat which involves organic matter decay, and also an impermeable sealing-mat. Each gas dome can last several days. Flipped-over mats are polygonal fragments of mat completely turned over at the edges, probably in the direction of tidal current, exposing the underlying substratum (Fig. 9(F)). The polygon is generally formed along weakness of crack network. Microbial chips are sedimentary features related to the physical mat-destruction that comprise eroded mat fragments, which reflect reworking and transport (Fig. 9(G)). Chips are irregularly shaped, flat-planar, often with rounded edges, and sometimes with flexible-cohesive behavior. These mat-chips are commonly seen spread all over the supratidal flat after storm events. Erosional pockets are derived from the mechanical destruction of the biostabilized sediment surface (Fig. 9(H)). These structures evolve from local destruction of the microbial mat that covered the surface sediment during high energy conditions generating irregular-shaped depressions with ripples features showing the difference in sediment colonization. Remnants are the flat-top surface portions biostabilized by microbial mats.

Other significant microbial structures were found in a modern environment, in an ancient tidal channel flooded only by a storm-induced high tide, so an intermittent high energy occurred. The sedimentary plain is colonized by thick leathery microbial mats (Cuadrado et al., 2015). Mainly, nonheterocystous filamentous cyanobacteria grow conspicuously in the upper mm of the plain surface, in order to find the optimal light intensity for photosynthesis. The microbial biomass in this mat was dominated by *M. chthonoplastes*, with their strongly entangled meshwork with polysaccharide sheaths particularly capable of binding particles. The interwoven filaments, trichomes, of these cyanobacteria produced a highly coherent structure, providing a dense and coherent fabric for the binding of sedimentary particles of 1–2-cm-thick (Fig. 10), giving to the microbial mat a remarkable external leathery appearance (Fig. 11). Water currents are the triggering mechanism to create deformed microbial sedimentary structures. Folds, rolls ups and flip over microbial structures are formed as a resulting of the flexible behavior and mat cohesiveness, under high shear stress, forming the deformed microbial sedimentary structures.

Concluding Remarks

Modern microbial mat communities comprise species that can inhabit in extreme habitats. These associations are well-adapted to a range of harsh conditions that include extremes of temperature, atmospheric pressure, salinity, pH, and nutrient deprivation. One of the best adapted groups to various extreme conditions is cyanobacteria which constitute the uppermost layer of organisms in microbial mats. In this chapter, the microbial mats described comprise most of the cases that are under some form of stress most of the time by intermittent flooding. That fact involves daytime stress of too much light and UV radiation, and desiccation. Modern studies had stated that they had evolved various strategies to survive with the harmful effect of high solar radiation at midday. The bluish-green cyanobacteria migrate some millimeters below the mat surface being protected by diatoms that contains a yellowish-brown pigment called scytonemin that absorbs up to 97% of UVA radiation. Moreover, most microbial eukaryotes and mainly cyanobacteria are known for withstand moderate to severe dehydration for prolonged periods of time, and they are able to recover from this stress (Castenholz, 2009).

Fig. 9 Sedimentary microbial structures formed in a tidal plain by the colonization of sediments. (A) Desiccation or shrinkage cracks are formed in the supratidal zone due to the solar radiation during the exposure of the microbial mats over several days. The rupture of the mat sometimes is alike a torn cloth displaying the filaments at the border of the crack. (B) Recolonization of wide desiccation cracks after a subsequent water inundation. (C) and (D) Gas dome and a broken one showing the hollow below. In (D) new little bubbles are form over the sediment inside the dome due to gases from photosynthesis. (E) Desiccation of gas dome probably formed by organic matter decay, surrounding by photosynthetic bubbles. (F), (G), and (H) Features due to erosion. (F) Flipped-over mats are formed after an increase in energy mainly where a former crack was present. Pencil as scale is 14 cm long. (G) Microbial chips formed by the erosion of microbial mat, transported, and laid down over the plain to be recolonized. (H) Erosional pockets and remnants as a consequence of a high level of energy that broken some parts of the colonized microbial mats.

Fig. 10 Scanning electron microscope (SEM) micrographs of microorganisms forming thick microbial mats in Paso Seco (Argentina). (A) A dense mesh-like arrangement of cyanobacteria. (B) Cyanobacteria trichomes and thick extracellular polymeric substances (EPSs) threads interwoven with pennate diatom frustules.

Fig. 11 Deformed sedimentary microbial structures present in Paso Seco (Argentina). (A) Microbial folds structures formed by the slippery thick and flexible microbial mat over the underlying sediment as a consequence of a high water current. (B) Microbial roll-up structure formed by the previously torn microbial mat and latter turn round by water current. Several involutions may happen. (C) View of large pond colonized by microbial mats where submerged flipped-over mats can be identified by the different color. The light brown mat is the recolonization of underlying sediment. The cracks present on the microbial mat can infer a previous subaerial exposure. (D) Close up of a fold microbial structure and the sediment underneath. The thick torn mat (1 cm thick) shows an oxic layer above (white arrow), an intermediate anoxic layer (dark layer, black arrow), and again an oxic layer below (white arrow) due to the air between the mat and the sediment underlying. Different laminae are forming the mat and the sediment below has the same form as the fold.

Biofilms and microbial mats work in sediments as cooperatives, not as solitary organisms, to respond to internal and external factors affecting the community (Noffke and Awramik, 2013). In fact, in a cooperative way the manner they increase their survival possibilities, and they find strategies to subsist in a damaging environment. Although not with exactly the same microbial groups present today, biofilms and microbial had evolved from the ancient times of Earth. Such structures as stromatolites and MISSs have existed since Archean times, demonstrating that microorganisms have been sustained throughout the geological record of life (Costerton and Stoodley, 2003). It is necessary to study the geobiological processes that take place in modern environments in order to be able to correctly understand what has happened during the geological past.

Introduction

The cellular membrane is a selectively permeable barrier between the cell and the extracellular environment. Cytoplasmic membrane transporters are a group of membrane proteins embedded in the phospholipid bilayer. These proteins typically contain multiple α -helical segments of usually 18–25 hydrophobic amino acids. These proteins mediate the movement of molecules and ions across the cytoplasmic membrane, and play essential roles in fundamental cellular processes like the acquisition of organic nutrients, extrusion of toxic and waste compounds, maintenance of ion homeostasis, environmental sensing and cell communication in archaea, bacteria and eukaryotes. Other transport proteins, such as those in the outer-membrane of Gram negative bacteria span the membrane as β -barrels. Based on current analyses, approximately 1–20% of open reading frames (ORFs) in prokaryotic genomes are predicted to encode membrane transport proteins, emphasizing the importance of membrane transport to microbes living in diverse environments. This estimated percentage range is broader than that listed in a previous edition of this book (published 2009) at both the upper and lower limits, which reflects the larger volume of genome sequence data available and the diversity amongst the strains that have now been sequenced. Knowledge of the suite of membrane transporters present in an organism is important to understand fully its metabolism and physiology, as well as its adaptation to a particular ecological niche (Fig. 1).

Various transport systems differ in their mechanisms of transport, membrane topology, energy coupling mechanism and substrate specificities (Fig. 2). Membrane **channels** form pores through the membrane that facilitate diffusion of water, specific types of ions or hydrophilic small molecules down their concentration or electrical gradient. This process is not coupled to metabolic energy and cannot transport substrates against their concentration gradient across the membrane. The rate of transport mediated by channels can be rapid, but will be related to the substrate concentration gradient and/or the transmembrane electrical potential in the case of charged substrates. Channels can have varying degrees of selectivity. For example, the narrow pores in channels may restrict passage to ions of the appropriate size and charge. Many channels, such as ion channels are not permanently open, a property referred to as gating; they open transiently in response to specific stimuli, e.g., the binding of signaling molecules (ligand-gated channels), changes in electric potential across the plasma membrane (voltage-gated channels), or changes in membrane tension (mechanosensitive channels).

In contrast to channels, active transport proteins require energy to mediate the movement of solutes across biological membranes. **Primary active transporters** energize transport via utilization of a primary chemical energy source, typically adenosine triphosphate (ATP) (Fig. 2). Transport involves the binding of specific molecules from one side of the membrane, then the transporter undergoes a conformational transformation that allows the substrate to pass through the membrane and be released on the other side of the membrane. It exhibits a much lower rate of transport and higher substrate stereospecificity compared to the channels.

The **secondary active transporters** also mediate energy-dependent active transport process, but utilize a pre-existing source of energy (e.g. an ion/solute electrochemical gradient). Secondary transporters can be differentiated on the basis of their transport mechanism, i.e., the mode of movement of substrate(s) and coupling molecule(s); uniport, symport or antiport (Fig. 2). Uniporters transport a single molecule without the involvement of a coupling molecule. Symporters transport substrate and coupling molecules in the same direction. Antiporters mediate the exchange of one or more substrates for coupling molecules.

A final group of solute transporters are the **group translocation systems** which modify their substrates during transport, exemplified by the bacterial phosphotransferase system (PTS) transporters (Fig. 2). PTS transporters typically enable the uptake of sugars from the external environment and concomitant phosphorylation and release into the cytoplasm as sugar-phosphates, using phosphoenolpyruvate (PEP) as both phosphoryl donor and energy source.

A great variety of substrates can be transported across the membrane by transporters. These include inorganic molecules; carbon compounds; amino acids and derivatives; bases and derivatives; vitamins, cofactors, signaling molecules and their precursors; drugs, dyes, sterols, and toxic substances; and macromolecules. Fig. 1 shows the predicted metabolic and transport capabilities of the soil and plant-associated bacteria *Pseudomonas putida* and provides an example of the complexity of transporters found in

[☆]Change History: May 2019. L. D. H. Elbourne, K. A. Hassan, Q. Ren, A. D. Cameron, P. J. F. Henderson and I. T. Paulsen updated the text and references.

This article is an update of K.A. Hassan, I.T. Paulsen, L.D.H. Elbourne, Q. Ren, A.D. Cameron, P.J.F. Henderson, Microbial Solute Transporters, Reference Module in Biomedical Sciences, Elsevier, 2014.

Fig. 1 Metabolic reconstruction of pathways present in the *Pseudomonas putida* genome. Transporters are grouped by substrate specificity as follows: inorganic cations (green), inorganic anions (pink), carbohydrate/carboxylates (yellow), amino acids/peptides/amines/purines/pyrimidines (red), and drug efflux and others (black). Question marks indicate uncertainty about the substrate transported. Export or import of solutes is designated by the direction of the arrow through the transporter. The energy-coupling mechanisms of the transporters are also shown: solutes transported by channel proteins are shown with a double-headed arrow; secondary transporters are shown with two arrowed lines, indicating both the solute and the coupling ion; ATP-driven transporters are indicated by the ATP hydrolysis reaction; and transporters with an unknown energy coupling mechanism are shown with only a single arrow. Components of transporter systems that function as multi-subunit complexes that were not identified are outlined with dotted lines. Where multiple homologous transporters with similar substrate predictions exist, the number of that type of transporter is indicated in parentheses. Systematic gene numbers (XXXXX) are indicated next to each pathway or transporter; those separated by a dash represent a range of consecutive genes. The outer and inner membrane are sketched in dark blue and dark green respectively, the periplasmic space is indicated in light turquoise and the cytosol in light green. Abbreviations are as follows: ADP, adenosine diphosphate; UMP, uridine monophosphate; UDP, uridine diphosphate; FucNAC, N-acetylglucosamine; Gal, galactose; GalNAC, N-acetylgalactosamine; GluNAC, N-acetylglucosamine; ManNAC, N-acetylmannosamine; NeurNAC, N-acetylneuraminic acid; P, phosphate; PP, diphosphate; Pyr, pyruvate. Reproduced with permission from Environmental Microbiology. Nelson, K. E., Weinl, C., Paulsen, I. T., et al. (2003). Complete genome sequence and comparative analysis of the metabolically versatile *Pseudomonas putida* KT2440. *Environmental Microbiology* 4(12), 799–808.

High-throughput genomic and metagenomic analyses are important to facilitate the study of membrane transporters. Instead of focusing on one or several transporter genes at a time, this type of study emphasizes the big picture, i.e. the complete transporter profile of an organism or a community of organisms. Examples include systematic annotation and classification of transporters, comparative study of the fundamental differences of transporter features amongst organisms with different evolutionary background, the association of genome transporter features with evolutionary history, physiology and lifestyle, and the integration of

transporter reactions into metabolic networks. In metagenomic studies the transporter profile of a community can be viewed within the context of the environment in which the community exists, e.g. in light of carbon or nitrogen source availability, or underlying selective pressures, such as contaminants or frequent disinfectant exposure.

In this chapter, we will review the features and functions of major transporter types and families, with the focus on recent progress in both structural and functional studies. We will also overview the bioinformatic classification of transporters as well as other types of comparative genomic studies of membrane transporters.

Transporter Classification and Annotation

Transporter Classification System

Transporters with similar functions characteristically cluster together in phylogenetic analyses. Thus substrate specificity appears to be a relatively conserved evolutionary trait in transporters. This has led to the premise that phylogeny can provide a rational basis for functional assignment. The Transporter Classification (TC) system and associated database, which is maintained by Milton Saier's research group at UC San Diego, represents a systematic approach to classify membrane transporter families according to their mode of transport, energy coupling mechanism, molecular phylogeny and substrate specificity (www.tcdb.org). The TC system is analogous to the Enzyme Commission (EC) system for classification of enzymes, except that it incorporates both functional and phylogenetic information. Transport mode and energy coupling mechanism serve as the primary bases for the classification due to their relatively stable characteristics. There are four major characterized classes of solute transporters in the TC system: channels, secondary transporters, primary active transporters and group translocators (described above; Fig. 2). Additionally, there are three other categories to catalog: proteins involved in the movement of electrons, accessory proteins, and transporters of unknown mechanism or function. These are shown in Table 1.

Each transporter class is further classified into individual families or superfamilies according to their function, phylogeny and/or substrate specificity. A specific transport protein can be represented by a TC number that normally has five components as follows: V.W.X.Y.Z. V (a number) corresponds to the transporter type (i.e., channel, secondary transporters, primary active transporters, group translocators, etc.); W (a letter) corresponds to the transporter subtype, which in the case of primary active transporters refers to the energy source used to drive transport; X (a number) corresponds to the transporter family; Y (a number) corresponds to the subfamily in which a transporter is found, and Z corresponds to the substrate(s) transported or to a specific transport protein. For example, the well-characterized *Escherichia coli* LacY lactose permease is represented in the TC system as 2.A.1.5.1, where "2" indicates it is a secondary transporter, "A" indicates it is a uniporter/symporter/antiporter, "1" indicates it belongs to the major facilitator superfamily (MFS), "5" indicates it belongs to an oligosaccharide symporter subfamily within the MFS family, and "1" indicates it is a lactose/proton symporter.

Table 1 The TCDB schema of transporter classes

Transporter class	Type	Description
1	Channels/pores	Energy-independent transporters that transport water, specific types of ions or hydrophilic small molecules down the concentration or electric gradient with higher rates of transport and lower stereospecificity compared to other transporter classes. Most ion channels, referred to as gated channels, open only in response to specific chemical, electric or mechanical signals.
2	Electrochemical potential-driven transporters (secondary transporters)	Secondary transporters (also called carriers) utilize an ion or solute electrochemical gradient, e.g. proton/sodium motive force, to drive the transport process. Uniporters move a single type of molecule down its concentration gradient. Antiporters and symporters couple the transport of ion or molecule against its concentration gradient with the movement of one or more different ions or molecules down its gradient.
3	Primary active transporters	Use the energy derived from a primary source of chemical energy (e.g. ATP hydrolysis) and move substrates across a membrane against a chemical concentration gradient or electric potential or both.
4	Group translocators	Modify their substrates during the transport process. For example, the bacterial phosphotransferase system (PTS) phosphorylates its sugar substrates using phosphoenolpyruvate as the phosphoryl donor and energy source and releases them into the cytoplasm as sugar-phosphates.
5	Transmembrane electron carriers	Mediate the flow of electrons from an electron donor to an electron acceptor in a biological membrane, and use the released energy to drive ion transport across the membrane and thus influence the membrane potential.
8	Accessory factors involved in transport	Indirectly influence the transport of solutes. These proteins may interact with transporters, assist in energy coupling or regulation.
9	Incompletely characterized transporter systems	Transporter protein families for which insufficient information is available to allow classification in one of the defined classes above.

TCDB: A Transporter Classification Database

Transport system families included in the current TC system are available in database format on the web. The TCDB site (<http://www.tcdb.org/>) provides detailed information and references for each transporter class, subclass, family, subfamily and individual proteins. When possible, these families are grouped into superfamilies that define the evolutionary relationships between individual families. TCDB also provides web-based search tools and various bioinformatic software packages that allow users to search by key word, gene name, family, or protein sequence. There is also a major section devoted to poorly characterized families of transport or putative transport proteins where more studies are needed.

TransportDB: A Comprehensive Database Resource for Transporters

TransportDB (<http://www.membranetransport.org/>) is a relational database, developed by Ian Paulsen's research group at Macquarie University, that catalogs all transport proteins encoded by organisms with fully sequenced genomes. Transport proteins are identified using the Transporter Automated Annotation Pipeline (TransAAP), which surveys fully sequenced genomes for genes encoding transport proteins using a variety of searches. It was created as a comprehensive database resource of information on cytoplasmic membrane transporters and Gram negative outer membrane channels in organisms whose complete genome sequences are available. The complete set of membrane transport systems and outer membrane channels in each organism is annotated based on a series of experimental and bioinformatic evidence and classified into different types and families according to the TC system. User-friendly web interfaces have been designed for easy access, query and download of the data (www.membranetransport.org). Features of the TransportDB website include text-based and BLAST search tools against known transporter and outer membrane channel proteins; comparison of transporter and outer membrane channel contents from different organisms; known 3D structures of transporters, and phylogenetic trees of transporter families. On individual protein pages, users can find detailed functional annotation, supporting bioinformatic evidence, protein/nucleotide sequences, publications and cross-referenced external online resource links. Another feature of TransportDB is the TransAAP web server where users can submit their genome or transporter annotation utilizing the high-throughput transporter analysis pipeline, view automatic annotation and supporting evidence, as well as curate the transporter annotation, all of which are through a user-friendly web interface.

TransportDB has now been in existence for nearly 20 years and continues to be regularly updated with new evidence and data from newly sequenced genomes, as well as having new features added periodically. As of November 2018, the TransportDB databases contain data from 2760 species, including 2557 bacteria and 164 archaea. Over 900,000 transporter proteins from these organisms were identified and classified according to the family designations described by TCDB. Some of these transport protein families are very large superfamilies with tens or hundreds of thousands of members, such as the ATP-binding cassette (ABC) superfamily, and the major facilitator superfamily (MFS), both of which are widely distributed in eubacteria, archaea and eukaryotes (Table 2). Others are very small families with only a few members present in a narrow distribution of organisms. The following sections look in detail at some representative membrane transport families.

Major Solute Transporter Families

Channels

KcsA, a potassium ion selective bacterial ion channel, was amongst the first membrane transporters to have their high resolution structure solved. Its structure was first reported in 1998 by MacKinnon's group utilizing X-ray crystallography, and later, the refined structure was reported at 2.0 Å resolution. The KcsA channel is a homotetramer with a fourfold symmetry axis forming the potassium ion permeation pathway. The N and C termini of each subunit are located inside the bacterial membrane, and contain two integral transmembrane helices, which are connected by a P-loop. The P-loop consists of a short helix that spans about 10 Å into the membrane and a loop region. It forms the selectivity filter, which is responsible for the selectivity for potassium ion over other ions. The structural studies of the KcsA channel, as well as other potassium ion channels (MthK, KvAP and KirBac), suggest the involvement of protein backbone structures in the selectivity process rather than individual amino acid residues, and illustrate the mechanism of high flux rate and selectivity for small polar and charged molecules across cell membranes.

Primary Active Transporters

The ATP binding cassette superfamily

The ABC transporter superfamily is characteristically one of the largest protein families found in the genomes of both prokaryotes and eukaryotes, with hundreds of thousands of identified members (Table 2). Most ABC transporters consist of four structural domains: two hydrophobic membrane-spanning domains that contain a variable number of membrane transmembrane α -helices (TMH), and two hydrophilic cytoplasmic nucleotide-binding domains that are responsible for ATP binding and hydrolysis to drive the transport process. ABC efflux systems are found in all domains of life, whereas ABC import systems appear to be prokaryote-specific and typically require an additional substrate binding protein. In Gram negative bacteria, this substrate-specific binding protein is periplasmic, whereas it is an extracellular lipoprotein bound to the membrane in Gram positive bacteria. ABC uptake

Table 2 The top 12 largest transporter families within bacteria and archaea in the TransportDB database

Family ID	Family Name	TC#	Occurrence ^a	Count
ABC	The ATP-binding cassette (ABC) superfamily	3.A.1	B,A	392,744
MFS	The major facilitator superfamily (MFS)	2.A.1	B,A	77,601
SSPTS	Sugar specific PTS	4.A	B,A	28,302
DMT	The drug/metabolite transporter (DMT) superfamily	2.A.7	B,A	24,229
F-ATPase	The H ⁺ - or Na ⁺ -translocating F-type, V-type and A-type ATPase (F-ATPase) superfamily	3.A.2	B,A	23,351
APC	The amino acid-polyamine-organocation (APC) family	2.A.3	B,A	16,351
RND	The resistance-nodulation-cell division (RND) superfamily	2.A.6	B,A	16,222
SSS	The solute:sodium symporter (SSS) family	2.A.21	B,A	14,482
MOP	The multidrug/oligosaccharidyl-lipid/polysaccharide (MOP) flippase superfamily	2.A.66	B,A	14,024
P-ATPase	The P-type ATPase (P-ATPase) superfamily	3.A.3	B,A	13,191
TRAP-T	The tripartite ATP-independent periplasmic transporter (TRAP-T) family	2.A.56	B,A	9704
IIISP	The type III (virulence-related) secretory pathway (IIISP) family	3.A.6	B	9399

Most of them are widely distributed in both bacteria and archaea, with the exception of IIISP (bacteria).

^aB, bacteria; A, archaea.

transporters are involved in the import of a diverse spectrum of solutes, including inorganic anions and cations, carbohydrates, amino acids and peptides. In these uptake systems the membrane-spanning and nucleotide-binding domains are typically encoded by distinct genes, which are often organized together in gene operons or clusters. ABC exporters in both prokaryotic and eukaryotic species are involved in the extrusion of various drugs, metabolites, toxins, lipids and signal molecules. In these systems, the membrane and nucleotide-binding domains are often fused into a single polypeptide.

ABC transporters are particularly abundant in prokaryotes, constituting up to 14.5% of all open reading frames (ORFs) (Table 3). Thermophilic *Thermotoga* bacteria devote some of the highest proportions of their genome to encoding ABC transporters (14.5%). These organisms lack a complete TCA cycle and an electron transfer chain, and therefore obtain their metabolic energy

from the fermentation of carbohydrates. They probably generate ATP as their primary source of energy through substrate level phosphorylation, and therefore ABC transporters are most frequently used to drive nutrient uptake and maintain ion homeostasis. Alphaproteobacteria also encode high numbers of ABC transporter proteins as a proportion of their total coding potential, e.g., *Agrobacterium*, *Ketogulonicigenium* and *Sinorhizobium* spp. The expansion of the ABC transporter family in these α -Proteobacteria may reflect an organismal requirement for high affinity transport since ABC uptake transporters can show higher substrate affinities than most secondary transporters by virtue of their substrate binding proteins.

The high-resolution structures of many intact microbial ABC transporters have now been determined, including uptake systems, for small (sugars, ions, etc.), or larger molecules (vitamins, metal chelates), and export systems (Table 4). The maltose transport complex in *E. coli* was one of the first and best-characterized members of the ABC superfamily and can serve as a general model for ABC sugar and other small molecule importers. In *E. coli*, the maltose transport complex is composed of a periplasmic maltose-binding protein (MalE),

Table 4 Bacterial and archaeal ATP-binding cassette transporters of known structure^a

Transport protein	Organism	TCDB number ^b	PDB number ^c
Solute uptake systems

a transmembrane complex made up of the MalF and MalG proteins, and two copies of the ATPase subunit, MalK. Transport of maltose is initiated by interaction of substrate-bound MalE with the periplasmic loops of MalFG, which induces a conformational change that results in ATP hydrolysis at the MalK subunits and eventually in the translocation of substrates. It has been shown that the ABC family maltose transport systems are widely distributed amongst Gram positive bacteria, Gram negative bacteria and archaea. This may be because maltose derived from starches in decomposing plant materials in the environment or the human gastrointestinal tract is one of the major sources of carbon and energy for heterotrophic bacteria and some archaea. In Gram negative bacteria, maltose uptake requires an additional protein on the outer membrane, LamB (maltoporin), to mediate the diffusion of maltose and maltodextrin into the periplasm. The genes encoding the maltose transporter components are usually clustered into closely linked operons. However, the ATP-binding component is often missing, suggesting a single ATPase could function with several transporters with similar functions. For example, the ATPase, MsiK can function in the uptake of maltose and cellobiose mediated by different ABC transporters.

The periplasmic substrate-binding protein MalE in *E. coli* can bind a variety of α -1,4-linked oligoglucosides, including linear, cyclic, reduced, and oxidized maltodextrins. However, only a fraction of the bound ligands are subsequently transported into the cell. The binding of *E. coli* MalE to substrates that are actively transported results in an endothermic reaction that is entropy driven, while the binding to non-transported substrates is an exothermic reaction. MalE has been crystallized in the presence of maltose or maltodextrin. Similar to other substrate-binding proteins, MalE consists of two symmetrical lobes, with a substrate-binding site positioned in a cleft in between. The MalE protein undergoes conformational changes involving the bending of a hinge that joins the two lobes. There is an open conformation in which the binding site is accessible to the substrate. The binding of substrate initiates a closed conformation in which the two lobes move toward each other and trap the substrate inside the cleft. Binding proteins have two roles in the transport: they are responsible for the high substrate specificity of transport, and they stimulate the ATPase activity. MalG and MalF are membrane-integral subunits with 6 to 8 hydrophobic TMH. They usually are less conserved than the ATP-binding domains. The presence of long inter-helical periplasmic loops in MalG and MalF represents a general feature of ABC transporters.

The nucleotide-binding domain (NBD), MalK, is located on the cytoplasmic side of the membrane. Two MalK proteins form a dimer in the complex and dissociate through ATP hydrolysis. The energetic motion of this process is believed to be communicated to the transmembrane domains to drive the transport reaction in both importers and exporters. The NBDs of ABC transporters are highly conserved. Structural studies have confirmed that a wide variety of NBDs share similar structures and that there is no clear distinction between importers and exporters in NBD structure. NBDs possess Walker A and B motifs that are characteristic of all P-loop ATPases, as well as a C-loop ("LSGGQ") signature motif, a D-loop ("SALD"), a Q-loop ("Q") and a H-loop ("H"). The crystal structure of MalK has been determined as a dimer in both nucleotide-free and ATP-bound forms, making it possible to visualize directly the MalK dimer in different conformation states. The two NBDs of MalK dimerize upon the binding of ATP in a "sandwich" pattern, with ATP molecules bound along the dimer interface, flanked by the Walker A motif of one subunit and the LSGGQ motif of the other subunit. Residues in these motifs are involved in extensive interactions with ATP and are required to form the ATPase active sites. MalK, as well as several other bacterial sugar transporters share a distinct feature: they contain an additional C-terminal domain of about 135 residues called the regulatory domain, which mediates the subunit-subunit interactions and contributes substantially to the dimer interface. The regulatory domain of MalK also interacts with regulatory proteins like enzyme IIA^{Glu}, part of the glucose phosphotransferase system and the transcriptional regulator MalT. A structure of the *E. coli* enzyme IIA^{Glu} in complex with MalFGK₂ has been solved (see section on "The Phosphotransfer-driven family" below for further discussion of EIIA proteins). The C-terminal domains of MalK maintain their intersubunit contacts all the time, while the N-terminal NBDs of MalK are in close contact only in the ATP-bound state. The motion of MalK implied by these structures is tweezer-like. The regulatory domains represent the handle that holds the two halves together, and the Q loops are located at the tips of the tweezers where they can move apart or together.

The 3.1 Å crystal structure of a putative archaeal molybdate transporter (ModB₂C₂) in complex with its binding protein (ModA) has also been reported (Fig. 3). This structure involved a single ModA subunit with bound substrate attached to the external side of ModB₂C₂, which allows unidirectional transport into the cytoplasm. Each ModB subunit contains 6 hydrophobic transmembrane helices, which form a total of 12 transmembrane segments in the transporter. The ModB subunits present an inward-facing conformation; a large cavity is formed by the two subunits facing the cytoplasmic side, which narrows towards the external membrane boundary and is closed by a gate beneath the interface with the binding protein (Fig. 3). This cavity, only accessible from the cytoplasm, is suggested to represent the translocation pathway.

Similar to other NBDs, the ATPase ModC subunits contain the highly conserved P-loops and LSGGQ motifs involved in ATP binding and hydrolysis. They are oriented in a head-to-tail arrangement, with the P-loops of one subunit juxtaposed to the LSGGQ motif of the other. In the nucleotide-free open conformation state, these motifs are separated by a gap. Also, during the open conformation, the attached binding protein ModA aligns the substrate-binding cleft with the entrance to the translocation pathway. Binding of ATP triggers a closed conformation. The observed spacing of the P-loops and the LSGGQ motifs in ModC is consistent with biophysical studies of the MalK transporter in which the solvent accessibility to the fluorescently labeled ATP binding sites is increased in the absence of ATP. The ModC-ModB interface transmits critical conformational changes, which links the ATP binding and hydrolysis to the transport process. Residues around the Q-loop of ModC primarily contribute to this interface.

In addition to these small molecule uptake systems, structures have also been solved for ABC transporters mediating the uptake of larger molecules, such as vitamins and metal chelates (haem), e.g., BtuCD(-F), HmuUV and HI1470/1, as well as for efflux systems (Table 4). In comparison to small molecule uptake systems, transporters involved in the uptake of large molecules display differences within the transmembrane domains, which are typically composed of a great number of TMHs (typically 10 per transmembrane domain).

Fig. 3 Front view of the ModB₂C₂A complex in ribbon representation, with the ModB subunits colored *yellow* and *blue*, the ModC subunits colored *green* and *magenta*, the binding protein ModA colored *red*, and with bound tungstate in van der Waals representation (*yellow* and *blue* spheres). The *gray* box depicts the probable location of the lipid bilayer on the basis of the hydrophobicity of the protein surface. N, amino terminus; C, carboxy terminus. Note that there is a vertical two-fold molecular and non-crystallographic symmetry axis for ModB₂C₂. Adapted by permission from Macmillan Publishers Ltd., Hollenstein, K., Frei, D. C., and Locher, K. P. (2007). Structure of an ABC transporter in complex with its binding protein. *Nature* **446**(7132), 213–216, copyright ©2007.

ABC efflux systems also display differences in their transmembrane regions compared with small molecule uptake systems. In these transporters the substrate specificity must come from the transmembrane domains themselves, unlike uptake systems, where this is dictated by substrate binding proteins. These exporters often function as multidrug transporters, capable of recognizing a broad range of structurally dissimilar lipophilic substrates. In line with this substrate recognition profile, the transmembrane domains can have been seen to create large central hydrophobic cavities when open inside to promote substrate binding, and hydrophilic cavities when open outwards to promote substrate release in the extrusion state.

Structural comparisons of ABC transporters of all these types share a common mechanism for ATP-driven transport, with binding of ATP promoting an outward-facing conformation (e.g., as in Sav1866) and dissociation of the hydrolysis products promoting an inward-facing conformation (e.g., as in ModB₂C₂A). Binding of two ATP molecules at the interface of the NBDs closes the gap between the conserved ATP-binding motifs. As this gap closes, so does the distance between the attached coupling helices, causing the TMDs to flip from the inward-facing to the outward-facing conformation. In uptake systems, this rearrangement may induce the conformation change of the attached binding protein, which force the two lobes to release the bound substrate. The substrate may then diffuse from the binding site through the open gate and into the translocation pathway formed by the transmembrane domain subunits.

Secondary Active Transporters

The major facilitator superfamily

The MFS is an ancient, large, and diverse superfamily of secondary transporters, which use an electrochemical gradient to drive substrate translocation across the membrane. They catalyze uniport in which one type of solute is driven across the membrane by its own substrate gradient, symport in which two or more types of solutes are pumped in the same direction simultaneously utilizing the electrochemical gradient of one of the solutes as the driving force, and antiport in which solutes are transported in opposite directions across the membrane. Most transporters in this family have 400–600 amino acid residues and usually possess either 12 or 14 putative TMH segments. MFS proteins exhibit specificity for a diverse range of substrates, such as sugars, sugar phosphates, polyols, drugs, neurotransmitters, metabolites, amino acids, peptides, osmolytes, iron siderophores, nucleosides, organic and inorganic anions.

The MFS transporters are very widespread across all three domains of living organisms. Like the ABC superfamily, MFS transporters are abundant in prokaryotes with more than 77,000 members identified to date in sequenced prokaryotic genomes, constituting up to 3.5% of ORFs (Table 5). The acidophile *Picrophilus torridus* encodes the highest percent of ORFs as MFS transporters (53, 3.5% of the total ORFs). Several other acidophilic archaea (*Thermoplasma acidophilum*, *Ferroplasma acidarmanus*), or acid-tolerant bacteria (*Lactobacillus fermentum*) were amongst the top five microbes in terms of MFS coding percentage (Table 5). Proton-driven transport mediated by the MFS may be energetically favorable for organisms in acidic environments. Only certain obligate intracellular organisms with highly compact genomes do not encode MFS transporters, for example *Phytoplasma asteris*, *Mesoplasma florum*, *Borrelia afzelii*, *Borrelia garinii*, *Treponema pallidum*, *T. whipplei*, *M. leprae*, and *Nanoarchaeum equitans*.

The tertiary structures of 13 bacterial MFS transport proteins (11 uptake and 2 efflux) have been solved, all of which are of the 12 TMH type (Table 6). The glycerol-3-P:P (GlpT) and the lactose-H⁺ (LacY) transport proteins from *E. coli* were the first of these MFS transporters to have their high-resolution three-dimensional structures determined. Despite their functional differences as an antiporter (GlpT) and symporter (LacY) and the differences in their amino acid sequences these structures revealed a similar twofold symmetry in the arrangement of the N-terminal six-helix bundle and the C-terminal six-helix bundle of each protein. Subsequent structures of MFS proteins, such as the fucose-H⁺ symporter or the EmrD antiporter from *E. coli* showed a similar overall protein fold, even revealing a further duplication of 3-TMH protein folds within each 6-TMH bundle.

One group of MFS transporters are particularly important for sugar metabolism throughout all organisms from microbe to man. They are known as the "Sugar Porter" (SP) family, 2.A.1.1 in the TCDB and recognize substrates like glucose, galactose, xylose, arabinose, inositols. The structures of several of these proteins have been resolved, including several from bacteria, such as a xylose-H⁺ symporter (XylE) from *E. coli*, and a glucose-H⁺ symporter (GlcP) from *Staphylococcus epidermidis*. As expected from the similarities in their amino sequences, their structures are very similar to each other, with an overall fold of the 12 TMH like that of GlpT and LacY and other MFS proteins, but with an additional 4-helix bundle in the cytoplasm formed from highly conserved motifs in their sequences. Most importantly, for XylE more than one form of the protein opening towards the periplasm or towards the cytoplasm has been described. Also, the position of the sugar binding site was established towards the center of the protein. A sequence of events can be deduced (Fig. 4) in which the protein, initially oriented towards the outside, closes around the ligand to yield a form occluded to both sides that then opens to the inside.

Despite the relatively low resolution of the XylE structures the changes in conformation accomplishing the alternating access transport of the substrate from outside to inside (or its reverse) can be visualized as mainly due to a rigid body movement of each of the N-terminal and C-terminal sub domains with respect to each other rather than differences within each subdomain (Fig. 4). Specifically, the subdomains undergo a tilting motion around an axis of symmetry roughly perpendicular to the plane of the membrane, resulting in tighter interactions at the periplasmic side and a wide opening appearing at the cytoplasmic side. In addition, in the outward-facing XylE structure, a helix bundle, containing motifs that are highly conserved in the SP family on the inside face of the proteins, interacts with the TMHs mainly via salt bridges, closing the exit of the substrate to the inside of the cell; in the inward-facing forms of XylE, these interactions are seen to be broken highlighting the important contribution of the motifs to mechanism.

Based on the structures of XylE taken with both the structures of the closely related glucose transporters and those of the less related transporters like GlpT, LacY, FucP and EmrD and a large body of biochemical and biophysical evidence, a mechanism is proposed for MFS proteins in which the transporter operates via a single binding site, alternating access model sometimes referred to as a "rocker-switch" mechanism. The substrate-binding site is accessible from only one side of the membrane at a time. Initially, the substrate-binding site is accessible from the extracellular space in the outward-facing conformation. The binding of substrate to the binding site induces a conformational change that exposes the substrate-binding site to the cytoplasm in the inward-facing conformation for release. It is reasonable to think that other MFS transporters maintain a similar basic architecture and substitute key residues in the substrate-binding site to change the specificity of the transporter.

Fig. 4 Structures of the XylE D-xylose- H^+ transport protein of *Escherichia coli*. The occluded forms would contain bound substrates, whereas the inward-facing open conformation would release substrates. The structures in the bottom correspond to PDB 4GBY (partially occluded outward open), 4JA3 (partially occluded inward open) and 4JA4 (inward open); models generated by M. Breidenbach. Figure and caption taken from Henderson, P. J. F. and Baldwin, S. A. (2013). This is about the in and the out. *Nature Structural & Molecular Biology* **20**, 654–655.

The 5-Helix Inverted Repeat Superfamily of Membrane Transport Proteins

An important development since the last couple of editions of this article is the realization that the separate families of transporters listed in Table 7 actually comprise a highly diversified superfamily of secondary transporters that, like the MFS, use an electrochemical gradient to drive translocation of a very wide range of substrates across the membrane by both symport and antiport, often with cations, commonly Na^+ or H^+ , and sometimes anions such as Cl^- and SO_4^{2-} . They are variously known as the LeuT superfamily, the amino acid-polyamine-organocation (APC) superfamily, or the 5-Helix Inverted Repeat Transporter (5HIRT) superfamily. We prefer the last because it is based on what is likely to be a generic structural feature in all members (see below).

The 5HIRT transporters are found across all three domains of living organisms. They are abundant in prokaryotes, with more than 50,000 members listed in TransportDB, including more than 16,000 and 14,000 proteins contributed by the Amino Acid-Polyamine-Organocation (APC) family and the solute:sodium symporter (SSS) family, respectively. A Na^+ -leucine transporter, LeuT, from *Aquifex aeolicus* was selected for detailed characterization and structural studies, because it is an easily over-expressed and crystallized homologue of human neurotransmitter transporters. Similarly, a bacterial homologue of human Na^+ -glucose transporters, vSGLT, from *Vibrio parahaemolyticus*, and bacterial homologues of human amino acid transporters from *Escherichia coli* and *Methanocaldococcus jannaschii*, were characterized for structural studies. Additional structures have been determined for the sodium-hydantoin transporter, Mhp1, of the nucleobase cation symport-1 (NCS1) family from *Microbacterium liquefaciens* and for the sodium-betaine symporter, BetP, from *E. coli* of the betaine/choline/carnitine transporter (BCCT) family (Table 7). Despite profound differences in their primary sequence, proteins from different families within the 5HIRT superfamily display similar 3D structures. Furthermore, according to the TCDB each of the families has some members with sufficiently similar aligned sequences of amino acids between different families for them all to have a common evolutionary ancestor. Taken together with similarities in their hydropathic profiles all the proteins of all the families are conceived to be members of the 5HIRT Superfamily.

Like members of the MFS most of the 5HIRT proteins are predicted to have 12 TMH. However, unlike the arrangement of two opposing similarly-folded six-helix bundles in the MFS with an axis of pseudo symmetry approximately perpendicular to the plane of the membrane 10 TMHs in the LeuT-like proteins are arranged in an *inverted* repeat fold in which the first 5 TMHs are topologically equivalent to the second 5 and are related to one another by a pseudo twofold axis that runs roughly parallel to the plane of the membrane. The two halves of the protein are completely intertwined with both contributing to the ligand binding site, which is situated buried in the membrane approximately at the centers of the respective proteins. Both MFS and 5HIRT types of protein achieve an alternating access mechanism of transport, but by very different conformational changes in structure. In contrast to the MFS rocker-switch mechanism, transport in 5HIRT proteins occurs via a “rocking-bundle” motion.

Insight into the latter mechanism was gained from the first protein for which the structure was determined in three conformational states, open-outwards, occluded with bound ligand, and open-inwards, the sodium-benzylhydantoin transporter, Mhp1,

Table 7 Transport protein families now thought to comprise the 5-helix inverted repeat superfamily of membrane transport (5HIRT) proteins

^cStructural homologues of LeuT (from Cameron, Beckstein and Henderson).

from *Microbacterium liquefaciens* (Fig. 5). A mechanism was derived for switching from the outward-facing open conformation through an occluded structure to the inward-facing open state. In this a bundle of the four helices 3, 4, 8, 9 known as the hash motif moves as a relatively rigid body with respect to a bundle of helices 1, 2, 6, 7 to provide the major element, the thick gate, of the switch from open-outwards to open-inwards (Fig. 5). Additionally a reciprocating movement of helices 10 and 5 closes an external thin gate and opens an internal thin gate (Fig. 5). A similar mechanism of the switching between outward- and inward-facing conformations caused by a rigid-body movement of the four-helix bundle relative to the rest of the protein was, in fact, first proposed for LeuT based on the asymmetry of the crystal structure and investigated more thoroughly using a mutational analysis of the serotonin transporter.

Can the fundamentals of the mechanism proposed for Mhp1 be extended to all the members of the 5HIRT (5 helix inverted repeat transporter) superfamily? This question is to some extent addressed by the recent structures of the LeuT transporter, which show outward, occluded and inward facing conformations of this protein. Like the mechanism above for Mhp1, the major change between outward and inward facing conformations is a rotation of the bundle relative to the hash motif. However, the details of the conformational changes are rather different between the two proteins. In LeuT there is no independent movement of TM5 or TM10 and instead the bundle helices are more mobile with TMs 1 and 6 flexing upon ligand binding and TM1 bending considerably as the protein changes from outward to inward facing. Similarly, by comparing the outward-facing AdiC with the inward-facing ApcT from the APC family or the occluded BetP with the inward-facing CaiT from the BCCT family, the trend of the hash motif moving relative to the bundle can be observed but the mechanism of occlusion is different. For example, in AdiC, which has been solved in the outward-facing and occluded states TM10, TM2 and TM6 move upon binding the ligand. Thus the mechanism for Mhp1 is to some extent

Fig. 5 The mechanism of Mhp1 taken from Shimamura et al. (2010). A, B, C The movements are delineated by arrows. (A) Helix 10 bends over the substrate. (B) The hash motif rotates by 30° around the rotation axis shown as a black line. (C) The small extracellular helix moves to seal completely the extracellular side of the protein. (D) Helix 5 bends to open the cavity on the intracellular side in a reciprocal manner to helix 10. (D–F) Surface representations of the three forms of Mhp1, showing the cavities in each. Figure taken from the supplementary material of Shimamura, T., Weyand, S., Beckstein, O., Rutherford, N. G., Hadden, J. M., Sharples, D., Sansom, M. S. P., Iwata, S., Henderson, P. J., and Cameron, A. D. (2010). Molecular basis of alternating access membrane transport by the sodium-hydantoin transporter Mhp1. *Science* **328**, 470–473.

observed in other members of the superfamily but the details vary, presumably reflecting the different substrates as well as the architecture of the non-core helices. Parallel studies of these proteins involving higher-resolution structures and mutational analysis combined with kinetic measurements are required if we are really to understand the general principles of the mechanism in this superfamily.

The Elevator Mechanism of Transport

The rocker-switch mechanism of transport, seen in MFS proteins, and the rocking bundle mechanism of transport, seen in 5HIRT proteins, such as Mhp1, are variations of the alternating access transport mechanism. In both mechanisms a substrate binding site that lies approximately mid-way through the membrane, is made alternately accessible to both sides of the membrane due to conformational changes that occur between protein domains to change the location of molecular gates around the substrate binding site. In the rocker-switch mechanism the domains surrounding the binding site are typically symmetrical, whereas the domains are usually asymmetrical in proteins operating via the rocking-bundle mechanism. Furthermore, the gates preventing access to the substrate binding site from one side of the membrane or the other are generally more complex in proteins operating via the rocking-bundle mechanism.

A third and distinctly different alternating access mechanism has been suggested to occur in a large number of transport proteins to have been structurally characterized over the past few years. This mechanism is referred to as the “elevator” mechanism of transport. In these proteins, the substrate binding site lies within one protein domain, which moves the substrate to the opposite side of the membrane past a centrally located molecular gate, formed against a second domain that is relatively immobile during the translocation cycle. The sodium-aspartate symporter from *Pyrococcus horikoshii*, Glt_{Ph}, was the first protein proposed to function via the elevator mechanism, and is supported by structural, biophysical and biochemical evidence. Remarkably, the substrate binding site in Glt_{Ph} appears to move approximately 18 Å across the membrane, relative to the immobile domain, during the translocation cycle.

Group Translocators

The Phosphotransfer-Driven Family

The phosphoenolpyruvate: sugar phosphotransferase systems (PTS) are complex enzyme systems functioning in the detection, transport and phosphorylation of various sugar substrates, including monosaccharides, disaccharides, amino sugars, polyols, and

other sugar derivatives. The phosphorylation of sugars in parallel with their uptake serves both to prevent their efflux and to prepare them for metabolism. The PTS family transporters use phosphoenolpyruvate (PEP) as the energy source and phosphoryl donor to carry out their catalytic function in sugar transport and phosphorylation. The basic components of the PTS (Fig. 6) are similar in all species studied. It is comprised of two general cytoplasmic components, enzyme I (EI) and phosphoryl carrier protein (HPr), which are common to all PTS carbohydrate transporters. The multi-domain enzyme II (EII) complex is sugar specific. Eubacteria usually encode many different EIIs. Each EII complex consists of one or two hydrophobic integral membrane domains (domains C and D) and two hydrophilic domains (domains A and B). The three or four domains together are responsible for the transport of the carbohydrate across the bacterial membrane as well as its phosphorylation. EII complexes can be formed either by distinct proteins or by a single multidomain protein. Likewise, fusion proteins that contain EI and/or HPr domains exist. A prominent example of the latter is FPr, which consists of HPr and an EI domain and mediates phosphoryl transfer during the uptake of fructose by *E. coli*, *Salmonella enterica* serovar Typhimurium, and *Rhodobacter capsulatus*. The PTS transporters are found exclusively in Gram positive and Gram negative eubacteria, and are absent in archaea and eukaryotes. *Coriobacterium glomerans*, *Sealdella termitidis* and *Lactobacillus casei* exhibit the highest number of PTS systems amongst all the sequenced prokaryotic genomes; each have about 50–60 EII complexes. About 15 different EII complexes are encoded in *E. coli* and *B. subtilis*. The properties of these enzymes have been established by various genetic, biochemical, and physiological studies. Paralogs of EI and HPr have also been identified in some species. For example, five paralogs of each general PTS protein were discovered in *E. coli*.

In a typical phosphoryl transfer reaction (Fig. 6), EI is phosphorylated using a phosphoryl group from PEP first, which initiates a chain of reactions. Phosphohistidyl-EI then phosphorylates a histidyl residue in HPr. This phosphorylation then transfers its phosphoryl group to a histidyl residue in EIIA of the sugar-specific EII complex. The phosphoryl group is then sequentially transferred to EIIB, and is finally transferred to the transported sugar bound to the membrane components, EIIC and/or EIID. All the phosphoryl derivatives in this multi-step phosphoryl transfer system exhibit similar energy. The phosphorylation occurs at either histidyl or cysteyl residues.

E. coli EI is a 63 kDa protein which contains about 570 residues, and is encoded by the *ptsI* gene. Sequence comparisons reveal significant similarities amongst EIs from various Gram positive and Gram negative eubacteria. EI is autophosphorylated in the presence of Mg^{2+} at the N-3 position of the imidazole ring of conserved histidine residue on the N-terminus of the protein, which also contains the binding site for HPr. The C-terminus of EI contains the PEP binding site and is required for dimerization. The structure of a full-length EI of *Staphylococcus carnosus* reveals that the N-terminal phosphohistidine and HPr-binding domain are

Fig. 6 General phosphoryl and sugar transport reaction catalyzed by the PTS. Sugars are transported and concomitantly phosphorylated by the PTS. See text for details.

clearly separated from the C-terminal dimerization and PEP binding domain. EI forms a homodimer that accepts the phosphoryl group from PEP. The inactive monomeric EI exhibits a relatively high structural variability. The dimerization and the binding of Mg^{2+} and PEP induce conformational changes that bring the C-terminal domain with the two bound ligands close to the active site, which is necessary to facilitate the phosphotransfer.

HPr is a small, heat-stable protein (about 90 residues, 9–10 kDa). It is encoded by the *ptsH* gene. HPr is phosphorylated at the N-1 position of the imidazole ring of a histidyl residue (His-15) by PEP and EI. In most low-GC Gram positive eubacteria and a few Gram negative organisms, HPr can also be phosphorylated by a regulatory ATP-dependent HPr(Ser) kinase on a seryl residue (Ser-46). This is not part of the phosphoryl transfer to carbohydrates, but phosphorylation of the seryl residue slows the phosphoryl transfer from EI to HPr at least 100-fold. *E. coli* HPr contains a Ser-46 residue but lacks an HPr(Ser) kinase. However, replacement of Ser-46 by an aspartyl residue significantly lowers the affinity of EI for HPr. The three-dimensional structure of HPrs from *E. coli*, *B. subtilis* and several other species are known. It forms an open-faced β sandwich consisting of four antiparallel β sheets that is covered at one side by one short and two long α -helices. The active histidyl residue (His-15) is located in the N-terminal part of the first long α -helix and is exposed to the solvent. The β sheet curls back on itself so that the regulatory seryl residue (Ser-46) is close to the active histidyl residue. Thus, the presence of the negatively charged phosphoryl group at Ser-46 may inhibit the phosphorylation at the active site by electrostatic repulsion or by inhibition of EI binding.

The carbohydrate specificity of the PTS is dependent on the EII complexes, which consist of integral membrane domains/proteins (EIIC/EIID) and cytoplasmic domains/proteins (EIIA/EIIB) (Fig. 6). The PTSs were classified into four superfamilies with distinct evolutionary origins on the basis of the phylogenies of the EII complexes: (i) the glucose-fructose-lactose superfamily, comprised of the glucose/glucoside family (TC 4.A.1), the fructose/mannitol family (TC 4.A.2), the lactose/diacetylchitobiose- β -glucoside family (TC 4.A.3), and the glucitol family (TC 4.A.4); (ii) the mannose/fructose/sorbose family (TC 4.A.6); (iii) the ascorbate-galactitol superfamily, comprised of the L-ascorbate family (TC 4.A.7) and the galactitol family (TC 4.A.5); and (iv) the dihydroxyacetone family. The sequence-based classification of the various PTSs is supported by X-ray crystallography and nuclear magnetic resonance (NMR) studies, which clearly show that the structures of the EIIA and EIIB domains/proteins belonging to the various classes are quite different. A representative structure for the EIIC membrane bound component has been solved from the *Bacillus cereus* diacetylchitobiose PTS permease (TCDB: 4.A.3.2.8; PDB 3QNQ). The structure shows a homodimer with one molecule of diacetylchitobiose bound in each protomer. Each protomer contains 10 TM helices and the protomer interface is comprised of the N-terminal regions and the sugar binding sites are formed by the C-terminal domains.

PTS also carries out numerous regulatory functions. The four proteins/domains (EI, HPr, EIIA, and EIIB) form a PTS phosphorylation cascade (Fig. 6) that can phosphorylate or interact with numerous non-PTS proteins and thereby regulate their activity. Indeed a structure of the ABC superfamily maltose uptake transporter MalFGK₂ has been solved in complex with a glucose specific EIIA protein (Table 4; PDB 4JBW). In this structure two EIIA proteins are bound to the MalK nucleotide binding domains and stabilize the inward-facing conformation of the transporter by preventing structural rearrangements required for ATP hydrolysis. The PTS regulation network not only controls carbohydrate uptake and metabolism but also interferes with the utilization of nitrogen and phosphorus and the virulence of certain pathogens. In *E. coli*, nitrogen enzyme I (EI^{Ntr}), nitrogen HPr (NPr), and nitrogen IIA protein (IIA^{Ntr}), paralogues of EI, HPr, and EIIA^{Trn} respectively, constitute a phosphoryl transfer chain that has been shown to exhibit little enzymatic cross-reactivity with the classical sugar-transporting phosphoryl transfer chain consisting of EI, HPr, and various sugar-specific enzyme II complexes. This nitrogen-related phosphoryl transfer chain presumably functions only in regulation. EI^{Ntr} homologues have been shown to cluster phylogenetically together, and distant from all other enzyme I homologues. EI^{Ntr} may serve a sensory function linking carbon and nitrogen metabolism. A mutation of the EI^{Ntr} gene resulted in impaired metabolism of poly- β -hydroxybutyrate, and diminished respiratory protection of nitrogenase under carbon-limiting conditions. In addition to EI^{Ntr} and NPr, *E. coli* encodes within its genome three additional EI paralogues and four additional HPr paralogues. The functions of most of these proteins are still unknown. A non-transporting enzyme II complex has been characterized in *E. coli*. It phosphorylates dihydroxyacetone (DHA) at the expense of PEP, using three soluble DHA-specific proteins (DhaK, DhaL, and DhaM), in addition to EI and HPr. The DhaM protein consists of three domains: an N-terminal IIA^{Dha} domain that is distantly related to IIA^{Man}, a central HPr domain, and a C-terminally truncated EI domain. All three domains can be phosphorylated by PEP with the EI and HPr as phosphoryl donors.

Genomic Analyses of Transporter Distribution and Function

Ongoing advancements in genome sequencing make it possible to conduct comparative analyses of essential cellular processes like transport in organisms across the three domains of life. Tens of thousands of prokaryotic genomes have been sequenced and deposited in the public databases. These genomes cover a broad range of microbial organisms from different phylogenetic groupings, allowing comparative genomic analyses across a diverse range of organisms and lifestyles. Genomic analyses of transport potential in a broad range of organisms has shown that both phylogenetic and environmental factors appear to influence transporter distribution patterns and databases such as TransportDB make this data accessible to all researchers. For example, queries made to TransportDB can identify groups of organisms that contain similar transporter profiles. These types of analyses have shown that organisms with a similar physiology or living environment, such as obligate intracellular organisms, plant/soil-associated organisms or autotrophs display similar transporter profiles. Each of these groups exhibit distinct patterns of transporter family distribution. The obligate intracellular organisms possessed the fewest types and number of transporters while plant/soil-associated organisms generally encode the largest variety and number of transporters of microorganisms examined. The cluster of

autotrophic organisms generally lack transporters for carbohydrate and organic nutrients while possessing a range of transporters for inorganic ions and molecules.

Beyond genome sequencing, functional genomic analyses, such as transcriptomics and proteomics, can be used to determine the relevance of different transport systems to physiological adaptations. This is based on the premise that transporters are generally held under tight regulatory control and are only expressed when required by the cell. These approaches can be particularly useful when the physiological carrier of a particular substrate is unknown, or when substrate(s) for given transporters, such as multidrug efflux systems, which are seemingly redundant in most microbes, are unknown. Additionally, in recent work transcriptomic analyses, coupled with biochemical and biophysical studies were used to identify a new family of drug efflux systems found mainly in proteobacteria (TCDB: 2.A.117.1: the (mainly) proteobacterial chlorhexidine efflux (PCE) family). An alternative approach for high-throughput functional characterization of transporters is via phenotypic profiling of libraries of mutant strains. This approach has been used to survey the substrates of putative uptake systems in mutant libraries of *Pseudomonas aeruginosa* and resulted in the identification of a novel histamine uptake system in this organism. Furthermore, high-throughput transposon mutant library screening approaches based on illumina sequencing, such as Transposon-directed insertion site sequencing (TraDIS), have allowed the identification simple genes mediating phenotypes of interest. Recent coupling of these approaches with flow sorting has led to systems that can identify transport proteins specifically involved in the transport of fluorescent substrates of interest.

Conclusions

The era of structural biology and genomics has opened new horizons in our understanding of complex biological questions. Three-dimensional transporter structures have provided us invaluable information on the mechanisms of transporter function. These structures have highlighted the alternating access model as being key to the mechanism of many diverse active transport protein families and the structures of these proteins in different conformational states have provided graphic detail of the intricacies of this process for several families. Comparative genomic approaches for the analysis of membrane transport systems have stimulated insights into how microbes adapt to their environment. The observations that organisms with similar lifestyles and/or ecological niches display similar transporter profiles despite their phylogenetic differences strongly suggest the influence of living environment on the complement of membrane transport genes in an organism. High-throughput functional analyses and functional genomic studies are being applied to address important gaps in our knowledge of transporter function and to identify novel substrates for the many putative transport systems identified in microbial genomes.

Introduction

The dairy industry is one of the most relevant in the food sector. It is characterized by a high diversity of products, obtained by applying different technologies. Especially cheeses can be considered the result of the meeting between tradition and innovation, since artisanal procedures have been “industrialized” to meet the global consumer demand.

Undoubtedly, microorganisms have an essential role in the dairy sector, especially for products, for which it is necessary to promote an acidification step in the milk, such as yoghurts and cheeses.

Microbial ecology in dairy products is very diverse and depends from the raw materials (e.g., raw or pasteurized milk), the processing technology (e.g., curd cooking, stay of the curd in the whey and pressing of the loaf) and the type of product (e.g., fresh, semi-ripened or ripened cheeses). However, several groups of microorganisms can be generally found in most dairy products, belonging to lactic acid bacteria (LAB), yeasts and filamentous fungi. LAB are responsible for the conversion of lactose in lactic acid, resulting in a reduction of milk pH, and they also produce hydrolytic enzymes, active on the protein fraction of the milk, able to release precursors of aroma compounds. Yeasts and moulds are important for their ability to produce proteolytic and lipolytic enzymes, which degrade milk proteins and lipids producing important compounds contributing to the final sensory characteristics.

There is a large body of literature that has described the microbial populations relevant in the dairy sector and there is a general consensus, in which LAB are divided in starter LAB (SLAB) and non-starter LAB (NSLAB). While the first group is responsible for the initial acidification of the milk and for the production of proteolytic enzymes, NSLAB possess specific metabolisms able to produce secondary metabolic compounds, which enrich the organoleptic profile of dairy products, especially yoghurt, butter and cheese. Yeasts and moulds are not involved in the acidification and they usually participate in the aroma formation through their enzymatic production. In the case of the molded cheeses, filamentous fungi are also responsible for the typical aspect and pigmentation of the cheeses.

In this article we will describe these categories of microorganisms, taking into account their role and ecology in the dairy products. Moreover, we will also discuss the advancements in the understanding of the microbial diversity by using molecular biology methods, which often have been applied without prior cultivation, thereby avoiding the biases of the traditional microbiological methods.

Starter Lactic Acid Bacteria

Over the centuries, cheese makers have domesticated fermentation processes empirically, without a deep understanding of the multiple biochemical reactions governing the sensory qualities of their cheeses. Nowadays, the role of microbiota in terms of metabolic activities has been mostly understood and many dairy productions are piloted and optimized by using starter cultures to standardize the fermentation process and reach the targeted properties for the final products.

Natural starter cultures (NSC) are produced daily, at cheese plant, by some form of backslipping and/or by application of environment selective pressure. Because no actions are used to prevent contamination from cheese making environment and raw milk, NSC are continuously changing, undefined mixtures of several species and strains of LAB (Parente and Cogan, 2004). Biodiversity is considered a strength point in NSC and producers of traditional cheeses, as Grana Padano and Parmigiano Reggiano, accept slight variability in their products as compromise with more peculiar and individual characteristics coming from their ability to manage wild populations in raw milk and whey starters (Gatti et al., 2014).

The concept of selected starter culture (SSC) is well established in the dairy sector, referring to homofermenting lactic acid strains, which produce lactic acid giving rise, with added rennet to curd formation. The mesophilic lactococci, mainly *Lactococcus lactis* subsp. *lactis* and *Lactococcus lactis* subsp. *cremoris*, generally make up around 90% of a mixed dairy starter population while thermophilic, mainly *Streptococcus thermophilus*, *Lactobacillus delbrueckii* subsp. *bulgaricus* and *Lactobacillus helveticus*, are employed in cooked curds because of their heat tolerance. Mesophilic cultures are used in the production of, for example, Cheddar, Gouda, Blue, Camembert, Edam, while thermophilic cultures are used for high temperature cooked hard cheese such as Emmental, Gruyere, Grana Padano and Parmigiano Reggiano (Beresford et al., 2001).

As reported above, the homofermentative *L. lactis* is the species mostly employed as mesophilic starter. The primary function of this microorganism, when inoculated into vat milk, is to produce acid, reducing the pH of milk to <5.3 in 6 h at 30–37°C. Moreover, *L. lactis* starter strains can be chosen also for their ability to metabolize citrate, during fermentation process, resulting in flavor production.

L. lactis is also involved in cheese ripening where its enzymes are involved in proteolysis and conversion of amino acids into flavor compounds (Beresford et al., 2001). The production of biopeptides by cell envelop-proteinases (CEP) has been studied in

L. lactis and showed high strain-dependent variability resulting in the production of peptides associated to different aroma (bitter, sweet, acid etc.) (Thierry et al., 2015). *L. lactis* contributes to cheese ripening either as intact cells, in early ripening, by means of its proteolytic enzymatic apparatus, and as autolyzed cells, during late ripening. On the basis of recent insights it has been hypothesized a role of *L. lactis* in VNC state, in cheese ripening, (Ruggirello et al., 2016).

In the last years, additional characteristics have been taken into account for the selection of new *L. lactis* strains to be added to starter cultures. Bioprotective properties have been studied by different authors. Renes et al. (2014) showed that the use of selected autochthonous *L. lactis* cultures reduced the content of biogenic amines in ewe's milk cheese, while Dal Bello et al. (2012) studied the ability of bacteriocin producing *L. lactis* strains to limit *Listeria monocytogenes* growth in Cottage cheese manufacturing.

Thermophilic starter strains, mainly belonging to *S. thermophilus*, *Lb. delbrueckii* subsp. *bulgaricus* and *Lb. helveticus* species are chosen according to their ability to acidify milk in the range of 50–55°C. Likewise, other properties related to texture, flavor, health have been taken into account, for their selection, in the last years.

Fuglsang et al. (2003) studied the production of bioactive peptides in various LAB, and found that *Lb. helveticus* strains, *in vivo* conditions, were able to produce antihypertensive peptides in sufficient amount to efficiently decrease blood pressure.

Stretchability has been also widely studied for its importance in the production of cheeses like Mozzarella and Emmental. This property was correlated, in *Lb. helveticus* and *Lb. delbrueckii* subsp. *bulgaricus*, to a low level of proteolysis accompanied by a low release of intracellular peptidases into the cheese aqueous phase (Sadat-Mekmene et al., 2013). Richoux et al. (2009) showed that qualitative more than quantitative aspects of proteolysis were determinants for the development of stretchability.

Finally, some authors investigated the ability of *S. thermophilus* strains to metabolize galactose. Galactose accumulation in cheese can favour the growth and CO₂ production by undesirable bacteria capable of galactose utilization. Despite most of *S. thermophilus* strains are unable to metabolize galactose, Umamaheswari et al. (2014) selected 6 strains Gal+ to be used to reduce the quantity of residual galactose in yogurt. Mukhurjee and Hutkins (1994) also ascribed the low residual galactose in mozzarella cheese using *S. thermophilus* in combination with *Lb. helveticus* in starter cultures.

Non Starter Lactic Acid Bacteria

Non starter lactic acid bacteria (NSLAB) are important constituents of the cheese microbiota during ripening. Conversely to SLAB, NSLAB are not involved in the milk acidification process or the curd formation, but are responsible for important biochemical modifications that take place during ripening of the cheese curd. They play an important role in aroma formation in hard cheeses while their presence may result detrimental for fresh or soft cheeses that do not undergo ripening. NSLAB most likely originate from raw milk and are thermo-tolerant enough to survive pasteurization and/or high temperatures used in curd cooking. Furthermore, they can colonize the dairy environment and equipment, also through biofilm formation, and therefore involuntarily inoculate milk and curd during cheese production.

During cheese ripening, complex and dynamic NSLAB consortia evolve. The kinetics of the different NSLAB populations depend on parameters such as initial load, environmental conditions (mainly temperature and humidity of ripening, salt concentration) and other technological aspects such as cooking, stretching of the curd, use of natural starters, ripening time (Gobbetti et al., 2015). NSLAB mainly consist of species belonging to the *Lactobacillus* genus. Oftentimes the term *mesophilic* lactobacilli is used to designate NSLAB and to distinguish the species mainly found during ripening from the thermophilic, SLAB responsible for the acidification. *Lactobacillus paracasei* and *Lb. plantarum* are considered predominant NSLAB species, but *Lb. rhamnosus*, *Lb. casei*, *Lb. fermentum*, *Lb. parabuchneri*, *Lb. curvatus*, *Lb. buchneri*, *Lb. brevis* and *Lb. pentosus* are important constituents of NSLAB consortia and frequently isolated from cheeses during ripening. The above mentioned *Lactobacillus* species are either facultative or obligate heterofermentative and have the metabolic capability to utilize both hexoses and pentoses or solely pentoses respectively. Although to lesser extent, other genera of LAB may be part of NSLAB consortia. *Enterococcus* spp. naturally occur in artisanal cheeses, mainly produced in Southern Europe (Giraffa, 2003). *Enterococcus* spp. are considered controversial microorganisms mainly due to demonstrated antibiotic resistance by members of this group, capacity to produce biogenic amines and presence of virulence factors within the genome of food associated *Enterococcus*. Furthermore, conversely to what has been proven for different *Lactobacillus*, no direct link between the presence of *Enterococcus* and specific modifications (chemical or other) in the product has been shown (Giraffa, 2003). Despite that, certain species, namely *E. faecalis*, *E. faecium* and to a lesser extent *E. durans*, have been found to dominate the NSLAB microbiota of cheeses and therefore are believed to contribute to the sensorial characteristics of the product. *Pediococcus* spp., mainly *P. acidilactici* and *P. pentosaceus*, have also been isolated from a variety of European ripened cheeses. *Leuconostoc* spp. are used as starter cultures for the production of Swiss type (for eye formation) and pressed ripened Dutch cheeses and to facilitate cheese openness in blue veined cheeses (Hemme and Foucaud-Scheunemann, 2004). Consequently, leuconostocs can be isolated from cheeses, produced with *Leuconostoc* – Containing starters, during ripening. Furthermore, they are isolated from a variety of raw-milk, as well as cooked curd and white-brined cheeses (Beresford and Williams, 2004). Isolates from raw milk cheeses mainly belong to *Leuc. mesenteroides* ssp. *mesenteroides*, *Leuc. mesenteroides* ssp. *dextranicum* and *Leuc. citreum* (Hemme and Foucaud-Scheunemann, 2004).

The cheese components that are potential substrates of NSLAB metabolism during ripening are: residual lactose, lactate and citrate, triglycerides that undergo lipolysis with liberation of free fatty acids (FFA) subsequently catabolized, and proteins (mainly the casein matrix) that undergo proteolysis to peptides and free amino acids (FAA) that, in turn, are further degraded (McSweeney and Sousa, 2000). The metabolic pathways and enzymatic reactions described above are not exclusively associated to NSLAB. SLAB, rennet added for the coagulation, the milk itself, as well as exogenous sources, contribute to the biochemical modifications

described during ripening. Residual lactose can be utilized by facultative heterofermentative lactobacilli as an energy source while citrate can be co-metabolized with sugars, by leuconostocs and mesophilic lactobacilli. The main products of citrate metabolism are diacetyl (produced in limited amounts), acetoin and 2,3 – butanediol; important flavor compounds for some cheese varieties. For Dutch cheeses citrate metabolism results in CO₂ production that leads to eye formation. Finally, acetate can be produced from lactose, lactate or citrate metabolism and is considered important flavor compound for many cheeses (McSweeney and Sousa, 2000). FFA that originate from lipolysis are important flavor compounds, indispensable for the sensorial characteristics of many types of cheeses. Short chain fatty acids have a direct impact on cheese flavor and are also precursors for the production of acids, alcohols, aldehydes, esters and thioesters, that further enhance flavor development (McSweeney and Sousa, 2000). Generally, non-starter lactobacilli, enterococci and pediococci have shown low lipolytic activity although important variability for this phenotype has been observed (Giraffa, 2003). For hard and semi-hard –type cheeses, casein proteolysis attributable to rennet enzymes and the microbial proteolytic system is an important biochemical pathway that leads to flavor formation (Smit et al., 2005). Through proteolysis, LAB are able to satisfy their amino acid requirements. Casein is mainly degraded by chymosin, endogenous milk enzymes and cell-envelope proteinases of SLAB that liberate peptides and amino acids. NSLAB are mainly responsible for peptidolysis and liberation of free amino acids. Peptides are hydrolyzed by intracellular peptidases and a wide variety of peptidolytic specificities has been described in non starter lactobacilli, pediococci and *Leuconostoc* spp (Beresford and Williams, 2004). Both peptides and amino acids possess specific flavor characteristics, however it has been underlined that the rate limiting step in flavor formation is the conversion of amino acids rather than their release through casein degradation (Beresford and Williams, 2004; Smit et al., 2005). Amino acid conversion ability varies within LAB and these activities are linked to the ability to synthesize amino acids (Smit et al., 2005). An α -ketoglutarate-dependent transamination reaction is the first step in amino acid break down. The resultant keto-acids are substrate for enzymatic or chemical reactions that lead to hydro-acids, aldehydes, carboxylic acids and alcohols; many of them flavor intensive molecules. Branched chain and aromatic amino acid transaminase activities, that are essential for flavor formation, have been detected in non-starter lactobacilli (Beresford and Williams, 2004). The amino acid conversion potential of certain non starter lactobacilli has been further confirmed by *in silico* analysis and comparative genomics focusing on pathways of flavor formation from amino acids (Liu et al., 2008). Decarboxylation is an alternative catabolic pathway for the pool of free amino acids that are available to LAB in cheese. Amino acid decarboxylation is believed to play a crucial role in pH homeostasis and allows microorganisms to respond to low pH stress conditions. The products of amino acid decarboxylation are CO₂ and primary amines. Some of these amines are volatile compounds that contribute to flavor and some cheese types contain numerous volatile amines (Zuljan et al., 2016). Amino acid decarboxylation reactions in cheese may also have a food safety implication. Biogenic amines produced by amino acid decarboxylation, when ingested in high quantities, can cause health problems. The most common biogenic amines found in cheese are tyramine, histamine and putrescine and the main producers are NS-LAB strains of the *Enterococcus* and *Lactobacillus* genera (Zuljan et al., 2016). Production of biogenic amines is strain dependent; therefore, careful management of the microbiota (both SLAB and NSLAB) throughout production should reduce the presence of these compounds in cheese.

An interesting trait that is common among LAB is the ability to produce bacteriocins. Bacteriocins have been defined as bacterially produced, small, heat-stable peptides that are active against other bacteria and to which the producer has a specific immunity mechanism (Cotter et al., 2005). Bacteriocinogenic LAB have been the focus of intense research since they can potentially be applied as biopreservation agents, active against foodborne pathogens or spoilage microbes in cheeses. Bacteriocinogenic LAB, belonging to *Enterococcus* and *Lactobacillus* spp, have been isolated from cheeses and were shown to have inhibitory activity towards important foodborne pathogens (for example *List. monocytogenes*, *Staphylococcus aureus*) and spoilage agents (for example *Clostridium* spp. responsible for the late blowing of hard cheeses) (Favaro et al., 2015). The antifungal activity of several species of *Lactobacillus* and *Enterococcus* is also of particular importance since fungal spoilage of dairy products is common and is currently dealt with using chemical preservatives.

Given the multifaceted attributes of NSLAB that influence the overall quality of the final product, the dairy industry is particularly interested in controlling the ripening process to achieve desired standards. For this purpose, NSLAB are often added as secondary/adjunct cultures. Strain selection for the development of such cultures is today sophisticated and takes into consideration not only technological properties but also safety characteristics, protective and probiotic potential.

Secondary Microbiota

In the definition of cheeses, different microorganisms are involved: longer than LAB population, other groups play fundamental role in the final character of the different cheeses. They are defined as the secondary microbiota, but of primary importance in the definition of peculiar characteristics.

The microbial diversity of the cheese depends on both the milk microbiota and on practices of production. This biodiversity decreases in the core of the cheese where LAB are the prevalent species, but it persists on the surface where numerous species are detected. The difference between cheeses is due particularly to changes in the dynamics of the microbial population used in the production. Cheese microbial population still remains difficult to control due to their complex dynamics and to their interactions (Artini et al., 2015).

The secondary microbiota significantly contributes to cheese characteristics, together with milk composition and starter and non-starter LAB activity (Bockelmann and Hoppe-Seyler, 2001) they are responsible for color, flavor and texture development during cheese maturing (Rademaker et al., 2005).

Propionic acid bacteria (PAB) are widely used in Swiss-type cheeses to generate holes and specific flavor notes, and surface bacteria that contribute to the characteristic flavor and color of smear-rind cheeses. Many of these properties depend on the strain within a species, and the choice of a selected strain is thus a means to modulate the final cheese properties (Thierry et al., 2015). The formation of flavor results from the conversion of milk lactose, citrate, caseins and lipids into taste and aroma compounds during the fermentation of dairy products. Propionibacteria is one of the important class of organisms used for the production of the Swiss cheese varieties. Swiss type cheese is a generic term for hard cheeses that were initially produced in Emmen valley in Switzerland and they are easily identifiable by characteristic round regular eyes. In this group of Swiss cheeses are included Gruyere, Maasdammer, Leerdammer, Emmental etc. Propionibacteria are often added to milk as adjunct cultures, but sometimes they are indigenous to the raw milk (Thierry et al., 2005).

Propionibacteria are Gram positive, non spore forming, anaerobic or aerotolerant and they possess several metabolic pathway: one of the most important is the central carbon metabolic pathway through which they use lactate during growth and produce propionate, acetate and carbon dioxide beside different functional metabolites like B group vitamins, conjugated linolenic acid (CLA) etc. (Hugenholtz and Smid, 2002). They are used widely as ripening cultures and different studies have also defined them as potential probiotic bacteria. They are involved also in the food preservation being microorganism able to produce antimicrobial compounds as bacteriocin and organic acids involved also in the antifungal activity.

Propionibacterium spp. was first discovered in 1906, when the relationship between the presence of *Propionibacterium freudenreichii* and the formation of holes in Swiss Emmental cheese was described. Indeed, *Pr. freudenreichii* together with *Pr. acidopropionici* are the principally used as an adjunct culture for the production and considered the most industrially important species (Poonam et al., 2012).

Focusing the attention on their technological attributes, they are mainly used as an adjunct culture for manufacture of Swiss type cheese where they are responsible for the characteristic flavor and eye formation. Beside this activity, they dominate the cheese microbiota during the ripening period (Rehn et al., 2011). However, their growth and fermentation rates in cheese depend on the conditions, in particular, NaCl content of the cheese (Richoux et al., 1998).

Eye formation is the result of CO₂ production during their growth, creating holes. On the other hand, flavor production is due to the metabolism of lactate (produced by LAB), aspartate and amino acid catabolism and fat hydrolysis. Volatile flavor compounds as 3-methylbutanal, 2-methylbutanal, and 3-methylbutanoic acid are produced by the catabolism of branched chain amino acids, particularly from leucine, isoleucine and valine (Poonam et al., 2012; Thierry and Maillard, 2002). They also produce FFA through lipolysis of milk fat. *Propionibacterium* species can also be used in the manufacture of some cheeses without eyes to enhance flavor formation: they can also modulate the flavor of Cheddar (Fernandez-Esplá and Fox, 1998), Raclette and Morbier cheeses (Thierry and Maillard, 2002; Thierry et al., 2005). The inclusion of PAB as starter affect substantially the volatile profile; their presence increase the levels of several compounds, such as branched-chain aldehydes, primary alcohols, branched-chain alcohols, diacetyl, acetoin, ethyl esters, branched-chain acids, and short-chain acids. The aroma formulation is connected to their inter- and intraspecies diversity in the production of aroma compounds as demonstrated by Yee et al. (2014).

As introduced above, *Pr. freudenreichii* in particular has a key role in the formation of the typical round holes (eyes). The correct formation of holes depends on physicochemical factors, such as the presence of nucleation sites for hole development, an appropriate cheese structure, a massive production of carbon dioxide that induces a local saturation of gas leading to the formation of holes. During the ripening in the warm room, *Pr. freudenreichii* produces CO₂ from lactate fermentation, thus producing the main part of the CO₂ formed in cheese, the remaining part being formed by facultative heterofermentative lactobacilli from citrate fermentation and amino acid catabolism (Thierry and Maillard, 2002).

In recent years, *Pr. freudenreichii* has been evaluated for its probiotic properties and it has been shown that it beneficially modulates the gut function and physiology (Thierry et al., 2011). Furthermore, Cousin et al. (2016), showed that *Pr. freudenreichii* can kill human colon cancer cells acting as a potential protective probiotic against gut cancer both *in vivo* and *in vitro*. The successful application of PAB as probiotics was recently demonstrated with milk fermented by *Pr. freudenreichii*, which induced apoptosis of HGT-1 human gastric cancer cells (Cousin et al., 2012). Recently (Angelopoulou et al., 2017) showed that *P. freudenreichii* could be used also in the production of Feta cheese.

Many cheeses are characterized by complex surface microbiota. Cheese rind ecosystem is in contact with the external environment and consequently differs from the cheese core in terms of microbial composition and biochemical characteristics (Irlinger et al., 2015). The surface microbiota has an important organoleptic impact on cheese thanks to its various enzymatic activities and its role as a barrier against pathogens and spoilage microorganisms. The structure of cheese rind communities differs between facilities and describes significant shifts in the microbiota between short- and long-ripened cheeses (Dolci et al., 2009; Schornsteiner et al., 2014).

During cheese ripening, complex microbial communities, generally referred to as smear, develop on the surface of some types of cheese. In fact, such cheeses, when exposed to air, naturally tend to develop a smear layer on the surface, typically consisting of yeasts and bacteria (Chapman and Sharpe, 1990). The composition of this bacteria, yeasts and moulds, depends on the cheese technologies, environmental conditions, such as temperature, humidity and salt, as well as on the microbiota of the brine and of the rooms in which cheese is ripened (Fontana et al., 2010). Due to extensive washing of the cheese surfaces with brine during ripening, bacteria-ripened cheeses are also known as washed rind cheeses and develop a red-brown glistening appearance called "red smear". The most widespread cheeses with this characteristic are Tilsiter or Limburger (Dutch production), Baufort and Munster (French) and Italian cheeses as Taleggio and Fontina (Corsetti et al., 2001; Dolci et al., 2014). In these cheeses, yeasts and moulds initially dominate the surface post-manufacture because they are acid-tolerant and salt-tolerant. The development of yeasts during the first

few days of ripening, which metabolize the lactate completely into CO_2 and H_2O , and forming alkaline metabolites, such as ammonia, induces an increase in the surface pH from 5 to 6 (Bonaiti et al., 2004). In addition, the production of growth factors by yeasts appears to promote the development of a Gram positive, catalase positive, salt-tolerant microbial communities composed mainly of coagulase-negative cocci (CNC) belonging to genera such as *Staphylococcus*, *Micrococcus* (Bockelmann, 2002) and coryneform bacteria (genera: *Brevibacterium*, *Arthrobacter*, *Microbacterium* and *Corynebacterium*) (Bockelmann et al., 2017; Corsetti et al., 2001). Traditionally, growth of the surface microbiota is initiated with the help of mature cheese, which release part of their surface into the smear tank (Bockelmann, 2002). The disadvantage is that pathogens or contaminants are also transferred to the smear tank to all the cheeses: the control of smear development on cheese surface is considered essential during ripening to reduce the risk of surface contamination by spoilage and pathogenic microorganisms (Bockelmann and Hoppe-Seyler, 2001). The knowledge of the microbial composition is also a prerequisite for the development of surface starter cultures. The surface starter culture could help in the preservation of spoilage microorganisms.

Generally this smear layer is undesirable in many hard and semi-hard cheeses, but is fundamental for soft and semi soft cheeses (Bockelmann, 2002). These smear microorganisms play a role in the ripening process, both through the action of proteolytic and lipolytic enzymes and the formation of many alkaline products that penetrate the body of cheeses.

Brevibacterium linens is one of the important surface microorganism that is present in the smear of surface-ripened cheeses and is commonly regarded as the organism primarily responsible for the characteristic taste, aroma, and color of surface cheese. *B. linens* was the first commercial smear culture and is today sold by all major starter culture suppliers (Bockelmann et al., 2017). The metabolism and physiology of this microorganism determine its growth on smear surface-ripened cheeses and the effect of such growth on the characteristics of the cheese (Meile et al., 2008; Motta and Brandelli, 2008).

More in general *Brevibacterium* spp. is a non-motile, non-spore formed, gram-positive coryneform bacteria that tolerates high salt concentrations (8%–20%), and is capable of growing in a broad pH range with an optimum at pH 7.0. They also survive carbohydrate starvation and drying for extended periods. Some strains of *Brevibacterium* produce distinctive red-orange carotenoid-type pigments when exposed to light during growth. The color of the colonies varies from orange (*B. linens*), through gray-white (*B. epidermidis* and *B. casei*) to purple (*B. iodinum*) (Jones and Keddle, 1986; Motta and Brandelli, 2008). (carotenoids) of the type-strain is often light dependent.

The interest in *B. linens* is connected to their ability to produce the self-processing extracellular proteases (Ratnayake et al., 1995), high levels of volatile sulfur compounds (Dias and Weimer, 1998a,b), bacteriocin (Motta and Brandelli, 2008), cell membrane-associated carotenoid pigment, and for their aromatic amino acid metabolism (Arrach et al., 2001).

Other important bacteria involved in the cheese definition and in the surface, are CNC composed mainly by *Micrococcus* and *Staphylococcus* genera. They are considered as positive biota involved in the development of organoleptic characteristic of the end products thanks to their proteolytic and lipolytic activities.

Among staphylococci, *Staphylococcus equorum* is one of the more predominant in cheeses. High cell count of staphylococci were found in brines of several cheese factories, explaining that brines are a natural source for cheese surface (Jaeger et al., 2002).

Except *Staph. equorum*, other several species as *Staph. cohnii*, *Staph. epidermidis*, *Staph. saprophyticus*, *Staph. xylosum* and *Staph. warneri* have been isolated from surface ripened cheeses (Bockelmann, 2002; Bockelmann and Hoppe-Seyler, 2001; Rea et al., 2007).

Staph. equorum was also isolated from milk and some types of cheese (Ercolini et al., 2003) and it was proposed as starter culture for Swiss semi-hard cheeses (Place et al., 2003) and smear-ripened cheeses (Bockelmann, 2002). *Staph. equorum* strains were isolated for their ability to produce bacteriocins and Bockelmann et al. (2017) showed that its cultures would be an ideal adjunct for cheese factories being able to inhibit *List. monocytogenes*.

The genus *Micrococcus* plays also important roles in cheese ripening due to its high proteolytic and lipolytic activities (Morales et al., 2006).

Yeasts and Moulds

As described above, dairy products are characterized by a high biodiversity in terms of bacterial populations, which are mainly responsible for the acidification and the production of aromas from proteolytic and lipolytic activities. However the complexity of these microbial ecosystems is enriched by the presence of eukaryotes, represented by yeasts and moulds (unicellular and multicellular/filamentous fungi). Compared to the bacteria, the yeast and mould relevant to dairy products are relatively limited and comprise genera and species able to ferment and assimilate lactose, utilize lactic and citric acids, grow at low temperature and in presence of high salt concentration, and able to hydrolyze milk proteins and lipids. *Kluyveromyces marxianus* (anamorph *Candida kefir*), *Kluyveromyces lactis*, *Debaryomyces hansenii* (anamorph *C. famata*), *Yarrowia lipolytica* (anamorph *C. lipolytica*), and *Saccharomyces cerevisiae* are the most isolated yeasts from dairy products (Frohlich-Wyder, 2003). Regarding filamentous fungi, *Penicillium camemberti* and *P. roqueforti* are used as starter cultures for the production of mould fermented cheeses (Haasum and Nielsen, 1998). Moreover, the yeast-like fungus *Geotrichum candidum* is also relevant for Camembert cheese production and some semi-hard cheeses, in which specific surface smear is developed.

Yeast and moulds are, however, also responsible for spoilage in dairy products. The species may differ or the same as the ones described above, moreover depending on the products from where they are isolated, they can be considered positive or negative.

Yeasts represent spoilage organisms in the dairy sector due to their ability to grow at low pH and low temperature. They are mainly involved in blowing of yogurt packages, through their fermentative metabolism, and they are responsible for anomalous

coloration of cheeses (mainly fresh), especially those producing pigments. Like yeasts, adventitious moulds should be considered spoiling agents of dairy products. They usually grow on the surface of the products due to their need of oxygen, thereby altering their aspect. However of specific concern is the capability of some species (e.g., *Aspergillus flavus*) to produce mycotoxins, which should be considered a risk for human health. The abundance and distribution of spoilage yeasts and moulds differ between products and within the same type of product manufactures have important role in the contamination. Even different batches of the same dairy product of the same manufactured can have different levels of spoilage yeasts and moulds (Banjara et al., 2015; Garnier et al., 2017).

Yeasts in dairy products are relevant to modulate the ecology of the cheese rinds, where they mainly metabolize lactic acid, thereby allowing the development of a complex microbial ecosystem composed by several bacterial groups, such as *Staphylococcus*, *Brevibacterium* and *Corynebacterium* (see above) and filamentous fungi. They are present in the raw materials, in the environment and the brine (smear water) represents an excellent carrier for their spread on the cheese surface. *Debaryomyces hansenii*, *C. versatilis*, *K. marxianus*, *Sacch. cerevisiae*, *Torulaspora delbrueckii*, *Trichosporon cutaneum* and *Y. lipolytica* are some of the most relevant species found in those ecosystems (Larpin-Laborde et al., 2011).

In fresh and short ripening cheeses, yeast ecology is represented by lactose positive species such as *K. lactis* and *K. marxianus*. In mould-ripened cheeses *D. hansenii* and *G. candidum*, as well as *K. marxianus* and *Y. lipolytica* dominate the mycobiota (Frohlich-Wyder, 2003).

In ripened cheeses, they contribute to sensory characteristics through the production of aroma from proteolysis and lipolysis, and they also play an important technological role in blue-veined cheeses where they produce CO₂ from the fermentative metabolism, which helps to maintain an open structure, allowing oxygen to penetrate in the loaf allowing filamentous fungi development. *Y. lipolytica* is recognized to have a great lipolytic activity (Groenewald et al., 2014), releasing fatty acids from triacylglycerols, that are important precursors of volatile compounds. Proteolysis is also an important role of dairy yeasts. *K. lactis*, *K. marxianus*, *D. hansenii*, *Y. lipolytica*, *G. candidum* and *C. catenulata* have been all characterized by their strong extracellular proteolytic and/or peptidolytic activity (Baur et al., 2015). Relevant to underline is their role in the brake-down of the bitter peptides, especially *G. candidum* (Auberoer et al., 1997).

Regarding the filamentous fungi, as already described above, they are mainly considered as spoilage agents, however some species are exploited in the dairy sector since they are taking part to the ripening of mould-ripened cheese. Specifically *P. camemberti* and *P. roqueforti* are used as starter cultures for the production of Camembert, Brie, Roquefort and Gorgonzola cheeses.

Penicillium camemberti in Camembert and Brie cheeses is essential for their characteristic appearance and sensory profile, since low-molecular-weight compounds produced by the fungus contribute significantly to taste. Volatile fatty acids, in particular, are produced from lipolytic activities important in soft cheeses, such as Camembert, where free fatty acids can reach up to 10% of the total fatty acids present. *P. camemberti* produces also proteases, involved as well in the development of the aroma profile. (Abbas and Dobson, 2011a).

Penicillium roqueforti is used as a fungal starter culture for the production of blue-veined cheeses such as Danablu, Gorgonzola, Roquefort, and Stilton. The fungus is involved in the production of both proteolytic and lipolytic enzymes. The proteolytic enzymes soften the curd and produce the desired body in the cheese. The water-soluble lipases hydrolyze the milk fat to free fatty acids, which contribute to the flavor of Blue cheeses (Abbas and Dobson, 2011b).

Culture-Dependent and Culture-Independent Approaches: What is Changing

Microbial communities in cheeses, at various stages of manufacturing and ripening, have been extensively studied by microbiological techniques based on the cultivation of microorganisms on selective media. This approach if allows, on the one hand, to obtain isolates to be studied for their phenotypic and genotypic characteristics, on the other hand, only a fraction of the community can be retrieved on cultural media. In fact, traditional agar-based and culture-dependent methods typically reveal the most commonly occurring microorganisms. These methods often underestimate the less abundant components of microbiota that could be equally important for cheese ripening and flavor development (Steel et al., 2006). To this regard, Neviani et al. (2009) optimized an innovative cheese agar medium able to recover minor populations, coming from milk, whey starter and fresh curd, in long ripened cheeses. Thus, alternative cultural approaches have to be investigated to obtain more reliable pictures of microbial community in dairy products.

The limits associated to culture-dependent techniques have led, in the last years, to the increasing use of culture-independent approaches, which depict a more reliable profiling (and also quantification) of microbial communities. Culture-independent methods overcome most of the cons associated to use of cultural media and they become essential in the study of microbial populations in physiological stressed state, included microorganisms in a viable but not culturable (VNC) state. Moreover, culture-independent techniques have shown high potentiality in the study of metabolic and functional genes strictly involved in the quality and safety of the final products.

Dairy Strains in Viable but not Culturable State

Bacteria in VNC state fail to grow on synthetic substrates on which they would normally grow and develop into colonies, but are alive and capable of metabolic activity. ATP levels have been found to remain high in VNC cells as also gene expression (Oliver, 2005). Thus, the role of microorganisms in VNC state has not to be underestimated and their presence has to be carefully taken into account.

LAB have been demonstrated to enter in VNC state under the stress conditions they can find during fermentation and ripening processes. In particular, sugar starvation has been recognized as a key stress for LAB (Ganesan et al., 2007). In those conditions, lactococci switch to the catabolism of amino acids and, potentially, contribute to flavor production during cheese ripening. Ganesan et al. (2007) have shown that *L. lactis* IL1403, in carbohydrate starvation, loses the ability to grow on solid media and expresses genes related to arginine catabolism. Thus, VNC cells, in ripened cheeses, remain intact and continue to metabolize peptides and amino acids to end products with a potential impact on cheese flavor (Weimer, 2011).

Studies on Swiss-Dutch-type cheeses showed that the physiological state of lactococcal starter cultures affect ripening and flavor development (Miks-Krajnik et al., 2013). Specifically, *L. lactis* populations, in VNC state, exhibited different metabolisms than in logarithmic growth phase and, around 30 days of ripening, their entering in VNC state was correlated to the simultaneously appearance of the branched-chain fatty acid C_{5iso}.

The presence of *L. lactis* cells in VNC state has also been hypothesized in some Italian cheeses, by Ruggirello et al. (2014). The same authors assessed, by culture-independent approaches, the persistence and viability of this microorganism throughout manufacturing and ripening of model cheeses where *L. lactis* populations were detected up to the sixth month of ripening (Ruggirello et al., 2016). On the contrary, from the analysis of the same samples, *L. lactis* was not found on selective media and this evidence, together with preliminary results obtained by resuscitation assays, corroborated the hypothesis it entered in a stressed physiological VNC state.

Community Profiling Methods: From PCR-DGGE to HTS

Since the 90s, methods in molecular microbiology have become a valid support to traditional techniques, in food analysis, and the trend towards culture-independent approaches have been considered a possible solution to problems associated with selective cultivation. Denaturing gradient gel electrophoresis (DGGE)-PCR has been, in the last twenty years, the most commonly used among culture-independent techniques, able to profile the diversity and dynamics of dominant microbial populations in many matrices, from environmental to food samples, included dairy products (Ercolini, 2004).

Genetic diversity of microbial communities, in dairy products, have been profiled by means of DNA-based protocols by different authors (Alegria et al., 2009; Bonetta et al., 2008; Casalta et al., 2009; Coppola et al., 2001; Ercolini et al., 2003; Flòrez and Mayo, 2006; Gala et al., 2008; Randazzo et al., 2010). PCR-DGGE technique has been carried out to fingerprint bacterial populations developing in raw milk cheeses manufactured without the addition of starter cultures, as in the case of Castelmagno PDO (Dolci et al., 2008, 2010) and Capo Verde cheeses (Alessandria et al., 2010). Moreover, it was also used in the study of the complex ecosystem of natural fermented Sicilian Ragusano-type cheese, giving useful information for starter culture design and preservation of artisanal cheese technology (Randazzo et al., 2002). The performance of selected and natural starters was also followed by PCR-DGGE in studies about whey cultures in Mozzarella cheese (Ercolini, 2004; Guidone et al., 2016) and in Caciocavallo silano cheese (Ercolini et al., 2008). This technique was also successfully used to determine the geographic origin of cheeses, such as Fontina, manufactured in alpine farms located at different altitudes (Giannino et al., 2009), Grana Trentino produced in different factories (Rossi et al., 2012) and Pecorino Crotonese from two areas (Randazzo et al., 2010). Mostly, PCR-DGGE and PCR-TGGE were performed to follow fate and dynamics of technological microbial populations; in addition, in a few studies, target microorganisms were related to cheese defects as late blowing (Cocolin et al., 2004; Le Bourhis et al., 2007).

Microbial RNA analysis has been also performed by RT-PCR-DGGE, but to a lesser extent, to obtain a picture of the species metabolically active at a particular sampling instant (Alessandria et al., 2010; Dolci et al., 2010, 2014; Masoud et al., 2011; Randazzo et al., 2002; Rantsiou et al., 2008). In particular, it was used to describe microbial communities characterized by a high complexity, as surface microbiota in Fontina PDO cheese (Dolci et al., 2013). In this study, RT-PCR-DGGE showed a major power than PCR-DGGE in describing biodiversity of Fontina PDO rind. Thus, the authors proposed that RNA molecules could have been considered a more informative target than DNA.

In the last years, several next-generation sequencing (NGS) technologies have been developed and applied to the study of dairy products reaching a high in-depth qualitative and quantitative profiling level, especially if compared to PCR-DGGE technique mainly focused on dominant populations (Ercolini, 2013).

Alessandria et al. (2016) explored the active microbiota during the manufacturing and ripening of a Grana-like cheese by beta-diversity analysis of the 16S rRNA sequencing data; Dalmasso et al. (2016) investigated the microbiota of Plaisentif, an artisanal antique cheese manufactured in the Italian Alps during the violet's blooming season. In another study, the bacterial diversity and structure of Mexican Poro cheese was analysed by 454 pyrosequencing in order to gain detailed insight about changes in bacterial communities associated with the cheesemaking process (Aldrete Tapia et al., 2014). Dolci et al. (2014) investigated bacterial dynamics, by both RT-PCR-DGGE and high throughput sequencing (HTS), during Fontina PDO cheese manufacturing and ripening, in relation to the different cow lactation stages, in order to evaluate a possible correlation between microbiota and phase of lactation. Quigley et al. (2012) carried out HTS to reveal the highly diversity of bacterial populations present in Irish artisanal cheeses, and detected several genera not previously associated with cheeses, specifically, goats' milk cheeses. HTS approach was also performed to investigate the microbial ecosystem of two artisanal smear-ripened cheesemaking plants (Bokulich and Mills, 2013); in this study, the authors demonstrated how environmental microorganisms dominated the surface microbiota of washed-rind products even in inoculated cheeses. Dugat-Bony et al. (2015) also collected metagenomic and metatranscriptomic data for a detailed overview of surface-ripened cheese microbial community, involved in cheese maturation. Finally, O'Sullivan et al. (2013)

reviewed nucleic acid-based approaches to investigate microbial-related cheese quality defects and underlined the potentiality of NGS in providing greater insight into structural community interactions and metabolic activities.

Lastly, the composition of cheese surface microbiota has been studied by the application of conventional culture-based analysis, by using culture-independent methods based on direct extraction of DNA/RNA from the matrices and by the application of HTS technologies. As reported by Irlinger et al. (2015), considering *Firmicutes*, *Staphylococcus* spp. was the most frequently genus followed by *Lactococcus*, *Enterococcus*, *Lactobacillus*, *Streptococcus* and among halophilic bacteria *Marinilactobacillus* and *Facklamia*. In the case of *Actinobacteria*, *Brevibacterium*, *Corynebacterium* and *Arthrobacter* were the most frequent genera followed by *Brachybacterium*, *Microbacterium*, *Agrococcus* and *Micrococcus*.

Technical issues in culture-independent methods concern nucleic acid extraction: nucleic acid yield, PCR inhibitors as various substances coming from cheese matrix itself, beside differential PCR amplification, are topics which have been widely reviewed (Ercolini, 2004; Wintzingerode et al., 1997). For these reasons, protocols have to be accurately optimized and adapted to extract nucleic acids from all different types of microorganisms and matrices. In particular, many efforts have been made to reach efficient RNA extraction from dairy matrices (Monnet et al., 2008). Authors agree on the necessity of high quality RNA from cheese as a prerequisite for reliable gene expression analysis in dairy microorganisms (Ulve et al., 2008; Ruggirello et al., 2014). In ripened cheeses, the presence of natural constituents such as lipids, proteins, carbohydrates and salt may render extraction very hard because they might act as PCR inhibitors.

DNA and RNA extraction optimization is fundamental when we move from the qualitative/semi-quantitative approach by PCR-DGGE, to the quantitative HTS (Quigley et al., 2012). The occurrence of each OUT can be negatively affected by an inefficient nucleic acid extraction in terms of quantitative estimation and proportions.

Furthermore, the choice of target molecule is critical for the success of any molecular profiling techniques. The target DNA sequence must include conserved sequences serving as anchors for PCR primers and, at the same time, it must be variable to differentiate microorganisms belonging to different species and genera (Bokulich and Mills, 2012; Jany and Barbier, 2008).

Bacterial community studies in cheese are based, mainly, on the analysis of 16S rRNA gene and 16S–23S intergenic region (Jany and Barbier, 2008). In particular, different sets of primers targeting the V3 hypervariable region have been extensively used (Delbès et al., 2007) and allowed identification at species or genus level. Differently, in fungi, the analysis of rRNA genes provides identification at genus or family level (Anderson and Cairney, 2004) and, thus, fungal internal transcribed spacers (ITS) are generally chosen as target for fungal community surveys inasmuch provide a greater taxonomic resolution than rRNA genes (Anderson and Cairney, 2004).

In HTS studies, when species assignment should be the target of the analysis, long sequence reads are required with as much as possible variable traits of 16S rRNA gene. Ercolini et al. (2012) studied the microbiota involved in the production of water buffalo mozzarella cheese by amplification of a 500 bp V1-V3 region and they reached identification at species level; differently, Alegria et al. (2012) used, as target, a 300 bp V5-V6 region to study Osypek cheese and the taxonomic resolution was at genus level. However, even with long reads, the 16S rRNA gene is not always heterogeneous enough for species discrimination in dairy bacteria, as observed in a research on Danish cheese where a 450 bp V3-V4 region was the target considered (Masoud et al., 2011).

In addition to the length of the target sequence, another technical issue is the copy number (Bokulich and Mills, 2012). For example, ribosomal RNA genes vary widely among taxa, skewing quantitative estimates. To circumvent this limit, alternative single-copy target sites, such as the *rpoB* gene in bacteria (Renouf et al., 2006), should be taken into account, despite the lack of representative sequence coverage poses a challenge for widespread implementation.

Quantitative PCR Approach: Detection and Quantification of Dairy Microorganisms and Study of Functional Gene Expression

In comparison with environmental microbiology, the use of molecular tools applied to the study of population dynamics and microbial gene expression in food is just beginning (Juste et al., 2008; Postollec et al., 2011). Quantitative PCR (qPCR) has become extremely popular in food studies, included researches on dairy products. Besides being faster than conventional culture-based methods, it is also highly sensitive and specific in the detection of microorganisms in dairy matrices; it has been also successfully applied in the study of sub-dominant populations even in absence of selective enrichment media.

An interesting multiplex qPCR protocol was optimized to simultaneously detect *Escherichia coli* O157:H7, *Salmonella* spp. and *List. monocytogenes* in milk samples (Omiccioli et al., 2009). Other interesting applications were in the detection and quantification of technological microorganisms, which positively affect the organoleptic properties of the final products. For example, Zago et al. (2009) followed sub-dominant populations of *E. gilvus* in cheese targeting *pheS* (phenylalanyl-tRNA synthase) gene; other authors (Furet et al., 2004; Grattepanche et al., 2005) quantified different LAB species in fermented milk, with detection limits between 10^2 and 10^3 colony forming units (CFU)/ml, in the presence of other dominant microbial populations. Quantitative PCR was also applied to study mycelial growth dynamics of *P. roqueforti* and *P. camemberti* (Le Dréan et al., 2010) whose presence is fundamental in mould surface-ripened cheeses. Despite the viable biomass was probably overestimated, in late ripening, the results allowed to monitor changes in fungal populations. The possibility to follow the growth, in real time, of specific microbial populations, in mixed dairy communities, opens the way towards industrial applications for the control of fermentation processes.

Beyond cell quantification, the detection of metabolic and functional genes, and also the study of their expression presents a novel use of qPCR; thus, for example, RT-qPCR is now being increasingly employed to follow microbial activity in dairy products.

The study of the expression of genes related to primary metabolism, or constitutively expressed in most of the cultural conditions, has been carried out by different authors. For example, Ulve et al. (2008) investigated seven genes of *L. lactis* inoculated in ultrafiltrated Cheddar cheeses, and demonstrated metabolic activity of lactococci even after several weeks of ripening. Similar results were obtained by Ruggirello et al., (2014, 2016) in the study of vitality and persistence, throughout cheese ripening, of commercial starters of *L. lactis* in both commercial and model cheeses by studying the expression of the housekeeping *tuf* gene. Moreover, the expression of *spxB* gene, encoding for pyruvate oxidase, was analysed by Sardaro et al. (2016) for monitoring the metabolically active community of *Lb.s casei* group involved in different ripening stages. RT-qPCR was also used in the elucidation of the dynamics, in Emmental cheese ripening, of *Lb. paracasei* and *Pr. freudenreichii* (Falentin et al., 2010). The results showed that *Lb. paracasei* began to grow in pressed curd and its metabolic activity reached a maximum during the first part of ripening, in cold room; *Pr. freudenreichii* began to grow from the beginning of ripening and its activity was maximum at the end of cold ripening while was stable during the first two weeks in warm room.

Quantitative PCR and RT-qPCR techniques has been applied to the research of metabolically active populations, either spoilage and pathogenic. For example, Martín et al. (2010) optimized an RT-qPCR protocol, based on *lacZ* gene, to detect coliforms in cheese, in a single reaction and within one day. In addition, other authors designed a qPCR protocol aiming to detect and quantify LAB carrying the histidine decarboxylase (*hdcA*) gene in milk and cheese (Fernandez et al., 2006). Despite LAB are non-pathogenic, however, in some environments, certain strains may produce undesirable compounds such as biogenic amines, which are responsible for food poisoning. Histamine is one of these compounds, resulting from histidine decarboxylation. Finally, a protocol to detect enterotoxin gene expression in *Staph. aureus*, artificially inoculated in cheese, was set up by Duquenne et al. (2010).

Thus, RT-qPCR revealed high potentiality in the elucidation of technological microorganisms roles in different stages, from cheese-making to ripening and, finally, conservation and storage of the final products, considering also the recent evidences related to the vitality of starter strains in late ripening (Dolci et al., 2010; Flòrez and Mayo, 2006; Rantsiou et al., 2008; Ruggirello et al., 2014; Ulve et al. 2008). Moreover, the impact of the different technological steps and parameters (temperature, pH, etc.) on the expression of target genes, linked to both primary and secondary metabolisms, could give additional interesting information. Finally, the detection and quantification of transcripts predicting for the presence of undesirable molecules and/or pathogenic and spoilage microorganisms could represent an efficient tool for microbiological control and risk assessment.

Conclusions

As described above, dairy microbiology is characterized by a high level of biodiversity involving different microorganisms, which interact in the same ecosystem. It is extremely important to understand how those events are taking place in order to have the possibility to control microbial activities that have a direct impact on the final characteristics of the end products. The use of molecular methods has given the possibility to better determine the taxonomy of a specific dairy ecosystem, however the challenges that we are facing at the moment is how to interpret and exploit this new knowledge to improve the safety and the quality of dairy products. An exiting future is expected for dairy microbiologists, who should be able to take advantage of these approaches to fully understand microbial diversity, activity and interactions.

Microbiology of the Cystic Fibrosis Airway

Cystic Fibrosis

Cystic Fibrosis (CF) is an autosomal recessive disorder and is the most common inherited life-shortening disease affecting Caucasians. It is a multi-organ disease caused by mutations in the CF Transmembrane Conductance Regulator (CFTR) gene on chromosome 7 which render the CFTR protein either ineffective or absent in those with CF (Welsh, 1986; Tsui et al., 1985; Riordan et al., 1989). The class II $\Delta F508$ CFTR mutation is by far the most common CFTR mutation and is caused by a deletion of a single phenylalanine at position 508 of the CFTR protein (Lukacs et al., 1994). CF patients homozygous for $\Delta F508$ ($\Delta F508/\Delta F508$) have a more severe disease phenotype including more frequent respiratory infections, an early onset of pancreatic insufficiency and decline in lung function (McKone et al., 2003).

The wild-type form of the CFTR protein is 1480 amino acids in length and is located on the apical surface of the epithelial cells of exocrine glands. The CFTR protein plays a vital role in osmotic balance in the lungs by mediating the translocation of negatively charged chloride ions out of epithelial cells while positively charged sodium ions translocate across the epithelial sodium channel (ENaC) (Ahmed et al., 2003). In CF chloride ion secretion is significantly reduced or absent, resulting in sodium hyperabsorption due to ENaC dysregulation (Stutts et al., 1995, 1997). The airway surface fluid becomes viscous, mucociliary clearance is impaired and the subsequent build-up of mucus creates an ideal environment for opportunistic pathogens to colonise and persist.

CF Airway Disease and Infection

Despite being a multi-organ disease, up to 95% of morbidity and mortality in CF is caused by airway infections and the associated inflammation (Zhao et al., 2012). CF is characterised by a cyclical pattern of infection, inflammation and airway obstruction. This leads to a build-up of irreversible lung damage and ultimately respiratory failure. The most common early symptoms include chronic cough, recurrent chest infections, breathlessness, and wheeze. Beyond the age of four months the pathological features in CF airways include inflammation, mucous plugging and bronchiectasis. Lung function is abnormal in CF infants shortly after birth (Kieninger et al., 2017). Early reductions in lung function are directly associated with microbial infection (Nixon et al., 2002) and microbial bioburden has been linked to increased inflammation. Dakin et al. (2002) Whether the lungs of people with CF are intrinsically inflamed from birth or become inflamed upon first exposure to microbes had been highly debated (Khan et al., 1995; Birrer et al., 1994; Balough et al., 1995). This stems largely from the detection of inflammation in the absence of culturable microorganisms from early CF sputum samples (Muhlebach et al., 1999) although more recent molecular detection techniques have shown that few CF airway samples are truly microorganism free.

Upon entry of bacterial cells to the healthy airways pathogen-associated molecular patterns (PAMPs) on bacterial cell walls are recognised by pathogen recognition receptors (PRRs) of circulating alveolar macrophages and lung epithelial cells which produce interleukin-6 (IL-6) and IL-8 (Bonfield et al., 1995), leading to infiltration of neutrophils (Conese et al., 2003). A cascade of chemokines, cytokines and activation of lymphocytes is triggered which elicits further inflammation. Alveolar macrophages and neutrophils can phagocytose bacterial cells and kill them internally within the phagolysosome. Neutrophils work to clear pathogens by secretion of proteases, such as neutrophil elastase (NE) and neutrophil extracellular traps (NETs), killing bacteria though causing epithelial cell damage in the process (Sorensen and Borregaard, 2016). Mass infiltration of neutrophils into the airways is a hallmark of CF disease and causes significant parenchymal damage (Ulrich et al., 2010). People with CF are not generally considered immunocompromised however the CFTR protein has been shown to act as a PRR for *Pseudomonas aeruginosa* (Pier et al., 1996) meaning this bacterium may be able to evade certain host responses. High levels of salt in the CF airway have been shown to impair activity of antimicrobial peptides (Smith et al., 1996; Goldman et al., 1997) and more recently CF neutrophils have been shown to have impaired function, including defective phagolysosomal fusion (Painter et al., 2006; Houston et al., 2013; Pohl et al., 2014). CF mast cells have been shown to release increased levels of IL-6 which can overstimulate neutrophil production (Ratner and Mueller, 2012). Inflammation and immunology of the CF airway is evidently very complex and is only briefly covered here. The following text gives a more thorough overview of defective immune responses in CF (Ratner and Mueller, 2012).

Microbiology of the CF Airway

Airway infections cause the burden of morbidity and mortality in CF (Gibson et al., 2003) and diagnosis of these infections forms the cornerstone of CF care. Diagnosis is largely based on the ability to culture these microorganisms from CF airway samples. The antibiotic resistance profiles of the cultured bacteria then informs therapeutic approach. Some of the most common bacteria isolated from the airways of people with CF are *Staphylococcus aureus*, *P. aeruginosa*, *Haemophilus influenzae*, *Stenotrophomonas maltophilia* and *Achromobacter xyloxidans*. Cultivation data has revealed a general pattern of succession with *S. aureus* and

Fig. 1 The 2016 Annual data report from the US Cystic Fibrosis Foundation Patient Registry. Reproduced from CFF, 2016. Cystic fibrosis foundation patient registry. Prevalence (%) of most common CF bacteria by age.

H. influenzae colonisation common in childhood, while *P. aeruginosa*, *S. maltophilia* and/or *Burkholderia* spp being more common in adults (Harrison, 2007; Pettigrew et al., 2008) (Fig. 1).

P. aeruginosa in CF

Prevalence

P. aeruginosa is a Gram negative rod shaped bacteria that commonly colonises the CF airways (Doring et al., 2000; Pitt et al., 2003). There is a chronology to *P. aeruginosa* colonisation in CF (Fig. 1). The prevalence in children has been reported to be anywhere between 20% and 97.5% (CFF, 2016; Lebecque et al., 2006; Burns et al., 2001; CFRI, 2016; Trust, 2016) while in adults it is between 52.5% and >80% (CFF, 2016; CFRI, 2016; Trust, 2016; FitzSimmons, 1993). One study reported that 29% of children with CF have acquired *P. aeruginosa* in the first 6 months of their life (Li et al., 2005). There have been conflicting reports on whether the prevalence rate of *P. aeruginosa* is decreasing in the CF population. A study in the US of the 1995–2005 CFF patient registry reported a 4.3% decrease in prevalence of *P. aeruginosa* in CF patients over the 10 years (Razvi et al., 2009) while a similar study carried out in the UK between 1985 and 2005 found no increase or decrease in prevalence (Millar et al., 2009). The 2016 CFF patient registry reported a decrease in prevalence between 1990 and 2016 however MDR *P. aeruginosa* prevalence remains constant (CFF, 2016) (Fig. 2). Reported prevalence differs depending on the detection method used (culture-based, molecular, serological), the age and disease status of the patient cohort and the country of the study.

The graph shows the proportion of individuals in various age groups who cultured positive for the bacterial species indicated during 2016.

Fig. 2 The 2016 Annual data report from the US Cystic Fibrosis Foundation Patient Registry. Reproduced from CFF, 2016. Cystic fibrosis foundation patient registry. Prevalence (%) of most common bacteria in CF between 1990 and 2016.

Infection, biofilms and persistence

P. aeruginosa infection is known to transition from initial sporadic colonisation to an intermittent infection, before becoming established as a chronic infection (Smith et al., 2006). In 2016, 46.9% of patients in the CFF registry were positive for *P. aeruginosa* of which 29.1% were chronic and 17.8% were intermittent (CFF, 2016). *P. aeruginosa* can adapt to the CF airway environment during infection changing from a non-mucoid motile phenotype to a mucoid, antibiotic resistant, biofilm former at which point it becomes almost impossible to eradicate (Doring et al., 2000; Hogardt and Heesemann, 2010). In early intermittent colonisation, *P. aeruginosa* in its environmental, non-mucoid and thus more motile state, can penetrate into thickened hypoxic mucus zones in the CF airway. Conversion of *P. aeruginosa* to mucoid growth and loss of motility are often seen as responses to stress (Deretic et al., 1994) and the physiological environment in the CF airway applies stresses such as osmotic imbalance, oxidative stress, immune cell responses, inter-species competition and antibiotic exposure. This results in diversification of *P. aeruginosa* genotypes in early and intermittent infection with the most favourably adapted descendants, usually mucoid biofilm formers, being selected for persistent colonisation (Jelsbak et al., 2007). Biofilms are assemblages of bacteria that adhere to and form microcolonies on surfaces, in this case CF epithelial cells or in mucus plugs, and are embedded in extracellular polymeric substances (EPS) which protect it from the surrounding environment. Biofilms are highly tolerant to the stressful environment of the CF airway (Smith et al., 2006; Jelsbak et al., 2007; Leid, 2009). Thus the ability of *P. aeruginosa* to adapt to the CF airway environment and grow in biofilms means it can evade host responses, avoid antibiotics and persist. Development of chronic *P. aeruginosa* colonisation is a significant disease milestone in CF and has been observed to mark the beginning of significant lung function decline (Pamukcu et al., 1995). Chronic *P. aeruginosa* colonisation is considered a major limiting factor in patient survival, with estimates of 10 years reduced life expectancy in chronically colonised patients (Li et al., 2005; Koch, 2002; Kosorok et al., 2001).

Virulence

P. aeruginosa has many virulence factors that help it invade and evade the host immune system. Secretion of phenazines and siderophores in addition to formation of biofilms have been known to result in poorer clinical outcomes (Jimenez et al., 2012). Pyocyanin is a phenazine produced by *P. aeruginosa* and is known to exert host inflammatory responses (Lau et al., 2004a,b; Fothergill et al., 2007) and act as an iron reducing agent (Pierson and Pierson, 2010). A study in CF mice reported an increase in pyocyanin levels during *P. aeruginosa* lung infection which was associated with more virulent infections mediated by tissue damage and necrosis (Lau et al., 2004b). A recent study investigating pyoverdine (a siderophore secreted by *P. aeruginosa*), pyocyanin and LasA (an elastolytic protease), concluded that high-virulence sub-populations of *P. aeruginosa* can persist in CF patients with chronic infections (O'Brien et al., 2017).

P. aeruginosa utilises its quorum sensing (QS) system to secrete virulence factors and to initiate biofilm formation by signalling between cells. In the early stages of infection *P. aeruginosa* utilises QS to determine high cell density and subsequently induces an upregulation of virulence factor-related gene expression (Bjarnsholt et al., 2010). Virulence factors are targets for immune cells, thus many strains of *P. aeruginosa* reduce their expression of virulence factors and extracellular toxins in chronic infections (Smith et al., 2006). Genes associated with QS, iron acquisition, phenazine biosynthesis, multidrug efflux and twitching motility have been found to be mutated to maximize survival and progression to chronic infection (Marvig et al., 2015). Under periods of severe stress subpopulations of *P. aeruginosa* biofilms can randomly convert to persisters, cells with reduced metabolic activity and increased stress tolerance. This is a vital survival mechanisms for *P. aeruginosa*. One study reported a 100-fold increase in drug-tolerant persister cells in late CF isolates when compared to the earlier CF isolates of the same clonal strain (Mulcahy et al., 2010). *P. aeruginosa* is an extremely adaptable microorganism and possesses a surprising number of virulence mechanisms for an opportunistic pathogen.

Epidemiology and transmission

Previously it was thought that CF patients carried their own individual strains of *P. aeruginosa* acquired from the environment however in 1996 a group in a CF centre in Liverpool reported that 55 of 65 paediatric CF patients harboured the exact same beta-lactam resistant epidemic strain of *P. aeruginosa*, the Liverpool Epidemic Strain (LES) (Cheng et al., 1996). Since then other epidemic strains have been reported in CF centres in the UK (Jones et al., 2001), Australia (Armstrong et al., 2003; O'Carroll et al., 2004) and most recently the priarie epidemic strain (PES) in Canada (Parkins et al., 2014). Clonal strains have been shown to be transmissible (Armstrong et al., 2003; McCallum et al., 2001), thus supporting the separation of *P. aeruginosa* positive and negative patient groups in the clinical setting. Many clonal strains of *P. aeruginosa* are multidrug resistant (MDR) (Jones et al., 2001; Ashish et al., 2012) and are associated with significant morbidity and mortality. CF patients colonised with LES have been shown to have greater annual loss of lung function than those not colonised with LES, but with unique strains (Al-Aloul et al., 2004). Somayaji R. and colleagues (2017) performed a 34 year clinical outcome study monitoring 274 CF patients and found PES was associated with a greater risk of death or lung transplant and the rate of lung function decline was greatest in the PES group (Somayaji et al., 2017).

Therapy and resistance

P. aeruginosa is intrinsically resistant to many antimicrobials due to its cell wall structure and its ability to express a wide variety of efflux pumps. *P. aeruginosa* can become resistant through mutation under selective conditions (such as the CF airway) and can also acquire resistance through uptake of plasmids, bacteriophage activity and transposons. *P. aeruginosa* possesses many multidrug-efflux pumps such as the MexAB-oprM pumps which extrude beta-lactams, quinolones and disinfectants, the MexXY-oprM pumps extruding aminoglycosides and the MexEF-oprN pumps extruding carbapenems and quinolones. Overexpression of the MexXY

pump is common in CF isolates (Singh et al., 2017) and a common mutational target in chronic CF airway infections is the multidrug efflux gene *mexZ* (Sobel et al., 2003).

Antibiotic sensitive strains of *P. aeruginosa* infections are usually treated with beta-lactams, such as ceftazidime, meropenem or an anti-pseudomonal penicillin combined with tobramycin or colistin (Trust, 2009). Colistin can often be reserved for treatment of more resistant strains of *P. aeruginosa*, as is often the case in chronic infection (Defez et al., 2004). MDR *P. aeruginosa* has been shown to arise due to exposure to antibiotics (Mohr et al., 2004). There is considerable susceptibility diversity within the *P. aeruginosa* population isolated from an individual sputum sample (and within colony morphotypes) (Workentine et al., 2013; Foweraker et al., 2005; Qin et al., 2018). This poses considerable complications when performing susceptibility testing in the clinical setting.

The ability of *P. aeruginosa* to adapt to the CF airway by increasing several virulence mechanisms and its intrinsic and adapted antibiotic resistance make it a very complex infection to treat. Early diagnosis and eradication are considered to be vital in delaying onset of chronic infection upon which morbidity and life expectancy are severely curtailed.

***S. aureus* in CF**

S. aureus is the most common Gram positive bacteria detected in people with CF (CFF, 2016; CFRI, 2016; Goss and Muhlebach, 2011). It is often the first bacteria isolated and is more common in childhood (Fig. 1). The prevalence of methicillin-susceptible *S. aureus* (MSSA) in children with CF (≤ 19 years old) in 2016 in Ireland was approximately 56.3% (CFRI, 2016), which is higher than the prevalence in the UK and US, 31.5% and 55%, respectively (Trust, 2016; Razvi et al., 2009). An average of 37.6% of children with CF in Ireland were recorded to be chronically colonized with *S. aureus*, whereas only 22.1% of adults were chronically colonised (CFRI, 2016). Prevalence of *S. aureus*, both MSSA and MRSA, is on the rise in the US (CFF, 2016) (Fig. 2).

Therapy and resistance

Since the emergence and dissemination of penicillin resistance in *S. aureus*, methicillin, cloxacillin and flucloxacillin have become first-line therapies. Narrow spectrum antibiotics such as flucloxacillin can be used as prophylactic drugs and dose can be increased if required. Flucloxacillin prophylaxis for children with CF is widely debated with countries and even clinics within certain countries differing in their approach. Prophylaxis is currently recommended from infancy in the United Kingdom (UK, 2009), advised against in the United States (Lahiri et al., 2016) while in Ireland there is no consensus, with individual clinics differing in their approach. There has been an increase in studies attempting to determine the benefit of anti-staphylococcal prophylaxis however there are contradicting outcomes (Stutman et al., 2002; Smyth and Walters, 2003). One trial reported no significant differences in clinical outcome between the placebo group and a trial group treated with cephalexin (5–7 year course), however it was noted that children treated with *S. aureus* prophylaxis were more likely to become positive for *P. aeruginosa* (Stutman et al., 2002). Conversely, other work has proven effective clearance of *S. aureus* and improved lung function upon anti-staphylococcal treatment (McCaffery et al., 1999).

MRSA

There has been a rising prevalence of methicillin-resistant *S. aureus* (MRSA) in CF in the US (~26%) (CFF, 2016) (Fig. 2) in the past 2 decades but not in Canada, Australia (2.6%) and Europe (2.6%) (Parkins and Floto, 2015). Methicillin resistance is caused by mutations in the *mecA* gene encoding PBP2A (a transpeptidase involved in cell wall maintenance) resulting in reduced affinity for penicillin and other beta-lactams. The *mecA* gene is present on a mobile staphylococcal chromosomal cassette (SCCmec) which means it is transferrable and 11 SCCmec types have been identified to date. MRSA has been shown to cause similar lung function decline and inflammation as *P. aeruginosa* in CF (Gangell et al., 2011; Sagel et al., 2009). MRSA infection can contribute to morbidity in CF patients, with an infected paediatric cohort showing impaired growth and an increased requirement for intravenous antibiotics compared to a non-MRSA infected cohort (Miall et al., 2001). In a large decade long analysis of over 17,500 individuals in the Cystic Fibrosis Foundation (CFF) Patient Registry, a more rapid decline in lung function was noted in those with persistent MRSA infection relative to controls (Dasenbrook et al., 2008). MRSA infection has been identified as an independent risk factor for failure to recover lung function following pulmonary exacerbation (PEX) (Sanders et al., 2010). Compared to patients with chronic MSSA infection or transient MRSA infection, those with chronic MRSA have an increased risk of death (Dasenbrook et al., 2010). Risk factors for chronic MRSA infection in CF include patient-specific factors such as genotype, level of pancreatic insufficiency, antibiotic use and comorbidities such as diabetes.

MRSA is resistant to β -lactams and often aminoglycosides and macrolides (Leski et al., 1999), thus it is recommended that tetracyclines and clindamycin are used, with glycopeptides and linezolid advised for more severe infections (UK, 2009). Linezolid, ceftaroline and tigecyclin resistant MRSA isolates have now been detected from CF airway samples (Champion et al., 2014; Long et al., 2014). New treatment strategies for MRSA in CF are being explored such as eradication strategies however it is uncertain whether eradication prevents development of chronic MRSA colonisation later in life (Dasenbrook et al., 2008; Dasenbrook et al., 2010).

Transmission

The anterior nares are a reservoir for *S. aureus*. There is some evidence of transmission of MSSA and MRSA from patient-to-patient (Garbacz et al., 2018; Givney et al., 1997; Schlichting et al., 1993; Muhlebach, 2017), between family members (Goerke et al., 2000) and siblings of CF patients (Elizur et al., 2007). It has been suggested that current MRSA infection management in CF should focus on controlling transmission (Muhlebach, 2017; Bell and Flume, 2017).

H. influenzae and *H. parainfluenzae* in CF

H. influenzae and *H. parainfluenzae* are among the most common Gram negative bacteria identified from the CF airway and are more prevalent in childhood. Both *Haemophilus* species are fastidious, non-motile, rods (or coccobacillus) and can form capsules which are important in virulence. Upon formation of biofilms, this bacteria exhibits reduced susceptibility to antibiotics, and thus can become chronic and cause lung damage (Starnes et al., 2006).

Approximately 30.6% of children (aged ≤ 19 years) were colonized with this bacteria in Ireland in 2016 (CFRI, 2016). *H. influenzae* is more prevalent in childhood than adulthood, with the prevalence for this bacteria dropping to an average of 7.9% in adults over 19 years of age (CFRI, 2016). This reflects colonisation patterns reported in the US (CFF, 2016) (Fig. 1). A 15 year study on 1528 *H. influenzae* and *H. parainfluenzae* isolates from 349 CF patients found that the prevalence of both bacteria and antibiotic resistance increased annually (Ebbing and Robinson, 2015). Cardines et al. (2012) found the majority of *H. influenzae* strains in their CF cohort to be nonencapsulated or nontypeable (NTHi), with many different genotypes identified. Genes involved in biofilm production and adhesion were persistent in *H. influenzae* colonising clones. There have been some reports of *H. influenzae* colonisation associated with lung function decline (Ramsey et al., 2014; Vandenbranden et al., 2012) while other studies have linked *H. influenzae* colonisation to preserved lung function (Hector et al., 2016). In a recent study *H. influenzae* was observed to have no link to inflammation in CF (Ratjen et al., 2016). The role of *H. influenzae* in exacerbation and disease progression is uncertain.

Colonisation with *H. influenzae* is generally treated with antibiotics such as co-amoxiclav or doxycycline for two to four weeks, to which most strains of *H. influenzae* are susceptible (UK, 2009). Resistances include azithromycin, amoxicillin and macrolides, while resistance to imipenem may be on the increase, though some resistant strains still remain susceptible to ampicillin (UK, 2009; Giufre et al., 2011).

S. maltophilia in CF

S. maltophilia is a Gram negative, MDR bacteria with a prevalence of up to 15% in CF patients in Ireland (CFRI, 2016) and a prevalence of 13.1% in the US in 2016 (CFF, 2016). It has been reported that prevalence of this pathogen is on the increase (CFF, 2016) (Fig. 2) however issues with the changing taxonomy of this species make these findings less reliable. CF patients can be persistently colonised with *S. maltophilia* over a number of years and can be colonised with numerous strain types at one time (Esposito et al., 2017).

S. maltophilia colonisation has been associated with poor clinical outcomes. One study found that CF patients positive for *S. maltophilia* had worse lung function than *S. maltophilia* negative patients (Goss et al., 2004). In a complimentary study IL-8, Tumour Necrosis Factor-alpha (TNF α) and *S. maltophilia* antibodies were higher while lung function was lower in patients with chronic *S. maltophilia* colonisation, compared to intermittently or non-*S. maltophilia* colonised patients (Waters et al., 2011). *S. maltophilia* colonisation has also been associated with a 3-fold increased risk of death and lung transplantation (Waters et al., 2013) and increased hospitalisation rates (Barsky et al., 2017).

Treatment of *S. maltophilia* is often based on co-trimoxazole due to its resistance to anti-pseudomonal drugs (UK, 2009). Though one study identified high rates of co-trimoxazole resistance *in vivo* and suggested doxycycline and a high concentration of colistin to be the most active against *S. maltophilia*, despite multidrug resistance becoming a common occurrence (San Gabriel et al., 2004).

A. xylosoxidans in CF

The true prevalence of *A. xylosoxidans* in CF is hard to establish largely due to disparities in taxonomy of the species. It has been named *Alcaligenes xylosoxidans* in the past and isolates currently defined as *A. xylosoxidans* may actually comprise multiple species. The CFF patient registry reported a prevalence of 6.3% in 2016 (Fig. 1) with prevalence remaining largely the same from 1990 to 2016 (Fig. 2) (CFF, 2016). Prevalence rates up to 11% have been reported (CFRI, 2016; Edwards et al., 2017).

Evidence suggests there is limited impact of *A. xylosoxidans* on clinical outcomes. Two studies have reported no association between *A. xylosoxidans* colonisation (either persistent or transient) and lung function decline (Edwards et al., 2017; De Baets et al., 2007). Edwards et al. (2017) observed no transmission events in a long-term genotyping study (Edwards et al., 2017) however transmission of a clone of *A. xylosoxidans* has been previously reported (Cools et al., 2016). Infection with *A. xylosoxidans* is generally transient with some reports of chronic infection.

Other CF Pathogens

Many other microorganisms are commonly found in the lung of CF patients including *Streptococci* spp, *Klebsiellae pneumoniae*, *Acinetobacter baumannii* and more rarely *Burkholderia cepacia* complex and *Mycobacteria* spp. Other bacteria detected in low frequency from CF airway samples include *Ralstonia* spp, *Pandoraea* spp, *Herbaspirillum* spp, *Bordetella* pp, *Moraxella* spp, *Serratia marcescens* and *Xanthomonas* spp (Coburn et al., 2015; Davies and Rubin, 2007; Lipuma, 2010; Rocha et al., 2018; Floto et al., 2016).

Streptococcus. This genus has been shown to be one of the core bacteria present in children with CF using molecular tools (Coburn et al., 2015; Zemanick et al., 2017). Sibley and colleagues identified several species in the *S. milleri* group (SMG) from CF airway samples (Sibley et al., 2010). In a recent large-scale single centre retrospective study of 381 CF adults, group B *Streptococcus*

(GBS) was found in only 3.5% of the patients (Skolnik et al., 2017). There were no shared strains among patients and patients colonised with GBS were not at increased risk of developing exacerbation and did not experience poorer lung function. The clinical significance of *Streptococcus* species in CF is uncertain although there have been some reports of SMG causing bronchopulmonary exacerbations (Parkins et al., 2008; Cade et al., 1999).

A. baumannii. *Acinetobacter* is becoming recognised as an emerging pathogen in CF, with one recent study identifying colonisation in 9% of samples from CF patients (Fernandez-Olmos et al., 2012). *A. baumannii* is phenotypically indistinguishable from those closely related species in routine laboratory technologies, thus the term Acb complex now covers *A. calcoaceticus*, *A. baumannii*, *A. seifertii* and *A. dijkshoorniae*. Recently over 50 different strains of *Acinetobacter* species were identified from CF sputum samples, many of which were MDR (Rocha et al., 2018). MDR carbapenemase-resistant strains of *A. baumannii* accounted for approximately 28% of all *A. baumannii* isolates in this study. These MDR strains may represent lineages which are a source of resistance genes with potential to spread to other pathogens in the CF airway. The current recommendation for treatment of *A. baumannii* infections is carbapenems, though a rising resistance has been documented (Karageorgopoulos and Falagas, 2008).

Burkholderia cepacia complex (Bcc) (Once called *Pseudomonas cepacia*) is a collection of phenotypically similar Gram negative bacteria, which differ by genotype and are divided into approximately nine species. Prevalence of Bcc in the US was 2.7% in 2016 (CFF, 2016). All nine species of *Burkholderia* have been detected in CF however *B. multivorans* and *B. cenocepacia* are the most common. Bcc infection can become chronic or even cause 'cepacia syndrome' which leads to a serious decline in lung function and can exhibit invasive disease (Mahenthiralingam et al., 2005). Epidemic strains have been identified in Canada (Johnson et al., 1994), the UK and Ireland (Pitt et al., 1996), the US (Chen et al., 2001) and several European countries (Drevinek et al., 2005; Campana et al., 2005). Implementation of appropriate infection control measures was demonstrated to eliminate transmission events (Chen et al., 2001). Bcc isolates from CF patients have been shown to be highly resistant to carbapenemases (Van Dalem et al., 2018) and ceftazidime-avibactam and ceftolozane-tazobactam (Van Dalem et al., 2018).

Mycobacteria. Non-tuberculosis mycobacterium (NTM) and most frequently *Mycobacterium avium* complex (MAC) (*M. intracellulare* and four *M. avium* subspecies) and *M. abscessus* complex (MABSC) (subspecies *abscessus*, *massiliense* and *bolletii*) are isolated from CF respiratory samples. In a large study of the UK CF patient registry an NTM prevalence of 3.8% in 2015 was reported and this had risen from 1.3% in 2010 (Gardner et al., 2018). A similar analysis of the US CFF patient registry from 2010 to 2014 reported 20% NTM prevalence of which 61% were MAC and 39% were MABSC (Adjemian et al., 2018). While the 2016 CFF registry report found 12.7% of patients in the US to be positive for Mycobacterial species (CFF, 2016). A recent whole genome sequencing study revealed that two MDR *M. abscessus* subspecies *massiliense* strains were transmissible among a CF population in the UK causing two outbreaks (Bryant et al., 2013). NTM can cause inflammation and a condition called 'NTM pulmonary disease' (NTM-PD) in CF but can also reside intermittently or persistently without causing any symptoms. MAC colonisation has been shown to negatively impact lung function in CF (Qvist et al., 2016). Considering the above and the difficulties in diagnosing NTM in CF, the CFF and European Cystic Fibrosis Society (ECFS) published a consensus recommendations document to standardise the management of NTM infection in individuals with CF (Floto et al., 2016).

Fungi in the CF Airway

Although much attention is given to the bacteria that colonise the CF airway, fungi are also important in CF lung infection. The most commonly isolated fungi from the CF airways include *Aspergillus fumigatus*, *Candida albicans*, *Scedosporium* spp., *Pneumocystis jirovecii* and *Exophiala dermatitidis*. The prevalence of fungi among CF patients varies significantly, ranging from 11% to 60% for *A. fumigatus* (Bakare et al., 2003; Valenza et al., 2008; Ziesing et al., 2016; Reece et al., 2017), 38%–78% for *C. albicans* (Bakare et al., 2003; Valenza et al., 2008; Ziesing et al., 2016; Noni et al., 2015a), for 3%–17% *Scedosporium* spp. (Sedlacek et al., 2015; Blyth et al., 2010), 12%–38% for *P. jirovecii* (Pederiva et al., 2012; Hernandez-Hernandez et al., 2012) and 1%–17% for *E. dermatitidis* (Horre et al., 2004; Kondori et al., 2014). Reported prevalence of fungi tends to vary greatly between studies depending on the method of detection used.

A. fumigatus. Of the *Aspergillus* species to colonise the CF airways, *A. fumigatus* is the most common, followed by *A. niger*, *A. terreus*, and *A. flavus*. Allergic bronchopulmonary aspergillosis (ABPA) is the most recognised fungal disease in CF and is caused by a Th2-mediated hypersensitivity response to *Aspergillus*. The prevalence of ABPA in CF is between 2% and 25% (Armstead et al., 2014; Maturu and Agarwal, 2015). A 2010 study reported chronic *A. fumigatus* infection was associated with significantly lower FEV₁% predicted (Amin et al., 2010). Itraconazole treatment of *A. fumigatus* colonised patients was shown to improve lung function suggesting a pathogenic role for *A. fumigatus* in CF (Chotirmall et al., 2008). Numerous studies have now concluded that CF patients chronically colonised with *A. fumigatus* had a more rapid decline in FEV₁ and in general experienced worse lung function than non-colonised patients (Reece et al., 2017; Noni et al., 2015b; Saunders et al., 2016). Gangell et al. (2011) carried out a study with 215 paediatric patients with CF and found those that were *Aspergillus* positive had increased inflammatory responses (neutrophils, neutrophil elastase and IL-8) compared to those who were *Aspergillus* negative. Although there are contradictory studies unable to link *A. fumigatus* colonisation to worse disease (de Vrankrijker et al., 2011).

A. fumigatus infection and ABPA in CF can be treated using posaconazole prophylaxis (Karthaus, 2011) or exacerbation therapy with systemic corticosteroids and azoles, most commonly itraconazole (Coughlan et al., 2012; Mahdavinia and Grammer, 2012). However there is no consensus on the treatment of *A. fumigatus* colonisation in CF with some clinics opting to treat upon positive culture and other only treating if symptoms of ABPA develop.

C. albicans. *C. albicans* has been associated with decreased FEV₁ and body mass index (BMI) and increased hospital-treated exacerbations (Chotirmall et al., 2010; Navarro et al., 2001). Baseline FEV₁ was also significantly lower and annual decline was significantly higher in patients chronically colonised by *C. albicans* compared to non-colonised patients. However other studies have not observed any negative association between *C. albicans* colonisation and lung function or BMI (Hector et al., 2016). It is likely that frequent use of antibiotics and steroids predispose CF patients to colonisation with this species (Noni et al., 2015a). Options for treatment of *C. albicans* infections include fluconazole and amphotericin (UK, 2009).

The CF Airway Microbiome

Traditionally, bacterial identification and detection were reliant upon selective and differential cultivation techniques. These practices could not account for fastidious and low abundance bacteria. In the past two decades culture independent approaches have revolutionised CF airway microbiology. The CF airway is now known to harbour a diverse community of bacteria (Sibley et al., 2006; Rogers et al., 2003), fungi (Willger et al., 2014; Delhaes et al., 2012) and viruses (Willner et al., 2009). The 'microbiome' has been defined as "the entire habitat, including the microorganisms (bacteria, archaea, lower and higher eukaryotes, and viruses), their genomes, and the surrounding environmental conditions" (Marchesi and Ravel, 2015). Molecular techniques such as T-RFLP, 16S rRNA gene cloning, Sanger sequencing and more recently next generation sequencing (NGS) have improved detection of previously unidentified genera such as *Streptococcus* and have identified anaerobic genera such as *Prevotella* and *Veillonella* as not only common in the CF airway but highly abundant (Zemanick et al., 2017; Rogers et al., 2003; Bittar et al., 2008).

The core microbiota of both adult and paediatric CF patients were recently defined by Coburn et al. (2015). The genera listed in Table 1 are commonly identified from the CF airway using molecular tools. Among these highly abundant genera, many are

Table 1 The most common conventional and emerging genera identified from the CF airway using molecular approaches

	Genus	Respiration
Conventional genera	<i>Achromobacter</i>	Ae
	<i>Burkholderia</i>	Ae
	<i>Haemophilus</i>	Ae, F

	<i>Sphingomonas</i>	Ae

Note: Ae = aerobic, An = anaerobic, F = facultative anaerobic.

considered non-classical CF pathogens and with a considerable amount being anaerobes. The relative abundances of these genera vary considerably depending on patient age (Coburn et al., 2015; Cox et al., 2010), different regions of the respiratory tract (Klepac-Ceraj et al., 2010; Renwick et al., 2014) and individual differences between patients (de Dios Caballero et al., 2017).

Patient increasing age is significantly correlated with decreased alpha-diversity (Cox et al., 2010; Klepac-Ceraj et al., 2010) and the risk of acquiring pathogenic organisms increases with age (Cox et al., 2010). The reducing community complexity in adult patients may be due to frequent disturbances to the ecological environment as CF patients are exposed to long-term, high dose antibiotics and indeed antibiotic usage has been associated with reduced diversity and *P. aeruginosa* invasion as patients age (Klepac-Ceraj et al., 2010). Some studies have shown that antibiotics impact the microbial community structure (Zhao et al., 2012; Klepac-Ceraj et al., 2010) while others have shown little influence of antibiotics on the overall diversity and community composition (Fodor et al., 2012). Antibiotic therapy directed towards *P. aeruginosa* has been shown to have little effect on *P. aeruginosa* bioburden but did significantly reduce the relative abundance of anaerobic species in the CF airway microbiome (Carmody et al., 2018). Repeated exposure to antibiotics most likely has an impact on the microbial community structure however whether this is transient or has long-term effects is still not known.

It is becoming increasingly evident that anaerobes are important in CF disease. In a 10-year study monitoring community composition fluctuations in 111 CF patients, diversity and the relative abundance of anaerobes increased during exacerbations and prior to antibiotic exposure in a disease stage dependent manner (Carmody et al., 2018). Conversely, a higher relative abundance of anaerobes has recently been linked to milder disease in CF with better nutritional status, pancreatic sufficiency and better lung function (Muhlebach et al., 2018) suggesting that these anaerobes may be beneficial in the CF airway. A study by Tunney and colleagues suggests a role for *Prevotella* species in shielding *P. aeruginosa* from antibiotics (Sherrard et al., 2016) which suggests a role for anaerobes in passive resistance.

Linking microbial community composition to measures of disease severity such as exacerbation and lung function is vital to establishing the significance of the microbiome in CF lung disease. Community composition fluctuations were monitored in a 10-year study of 111 CF patients (Carmody et al., 2018). Changes to the microbiome during exacerbation were shown to be largely dependent on community composition and diversity at baseline, with particular genera such as *Pseudomonas* and *Gemella* acting as important drivers of change (Carmody et al., 2013). In a climax-attack model established by Carmody et al. (2013) dominant pathogens in the microbiome, such as *P. aeruginosa*, were found to decrease with the onset of symptoms while overall diversity increased (Carmody et al., 2013). The climax or baseline microbiota consisting of typical CF pathogens and the attack/ exacerbation community being dominated by anaerobes such as *Prevotella*, *Veillonella*, *Fusobacterium* and microaerophilic *Streptococcus*. Alternatively other studies have shown there to be little change in microbial community composition in patients during exacerbation and when these patients were clinically stable (Fodor et al., 2012; Cuthbertson et al., 2016). While the link between exacerbation and microbial community composition is not clear, poor lung function is clearly correlated to reduced microbiome diversity as has been published in a number of studies (Delhaes et al., 2012; Acosta et al., 2017; Stressmann et al., 2012).

Microbial Interactions in the CF Airway Microbiome

We now have a more comprehensive view of the microbiology of CF airways and co-infections involving different species of bacteria probably represent the norm in the CF lung. Dominance of the CF airway by specific pathogens, particularly *P. aeruginosa*, has been shown to impact microbial community diversity (Klepac-Ceraj et al., 2010; Renwick et al., 2014). How *P. aeruginosa* colonisation changes the surrounding microbiome and indeed how diverse members of the community interact in general is not well understood. Some studies have begun to shed light on the polymicrobial interactions taking place among these bacteria (Table 2). These studies provide evidence that inter-species and cross-Kingdom interactions can influence not only pathogen virulence but also host responses. The impact of these interactions in CF airway disease are yet mostly unexplored.

Summary

CF airway microbiology is complex and while some microorganisms such as *P. aeruginosa*, have a clear role in inflammation and disease progression, the role of other microorganisms is less clear. With the increased sensitivity of molecular techniques the diversity of microbes colonising the CF airway is becoming apparent. Several studies have found anaerobes to be highly prevalent and abundant in the CF airway. While other studies are identifying an ever increasing number of “emerging species” previously not known to colonised the airway. Care must be taken in interpreting the significance of low abundance microorganisms as the lower airway microbiome is low density and this brings technical issues with distinguishing true microbiome from background noise and contamination. Nevertheless, the discovery of these complex communities has revolutionised CF airway microbiology and highlighted the potential for inter-species and cross-kingdom interactions to influence host immunity and thus disease progression. Many groups are now focusing on using bioinformatic tools and *in vitro* models to further tease out symbiotic, mutualistic, competitive and antagonistic relationships within microbial communities and how they may impact disease (Magnusdottir et al., 2017; Shah et al., 2016). It is evident that the CF airway breeds diverse, adapted and resistant microbial phenotypes and with this comes infections that are extremely challenging to treat. Understanding more about the complex airway microbiome in chronic lung diseases may provide alternative avenues for developing novel therapeutic approaches in the future.

Table 2 Studies reporting microbial interactions with *P. aeruginosa*

Species interacting with Pa	Microbial/host response	Potential implications on disease	Ref(s)
Gram positives	↑ lytic activity by Pa ↓ Gram+ in <i>in vivo</i> models ↑ pyocyanin production by Pa	Pa more toxic in co-infections with Gram+ Pa mechanisms of dominance	(Korgaonkar et al., 2013) (Korgaonkar and Whiteley, 2011)
<i>S. aureus</i>	Co-infection strains less competitive than mono-infection strains Pa induces bronchial epithelial cells to produce phospholipase, sPLA2-IIA Pa EPS can affect mixed species biofilm architecture	Adaptation to coexistence in the lung Manipulation of host immune response, enhanced survival of Pa and killing of Sa Proximity of Sa and Pa in mixed biofilms	(Reece et al., 2018) (Pernet et al., 2014) (Chew et al., 2014)
<i>S. maltophilia</i>	↑ Pa siderophore production Pa LPS inactivation mutations ↑ resistance of Pa to B-lactams Co-colonise the CF airway ↓ Sm growth ↑ Pa biofilm ↓ Adhesion of Pa to CFBE ↑ tobramycin resistance of Sm in mixed biofilms ↑ tolerance of Pa to polymixin	Iron competition Reduced recognition by immune system, persistence Resistance Opportunity to interact in airway Altered virulence and persistence Evading of immune system and persistence Resistance Resistance	(Tognon et al., 2017) (Tognon et al., 2017) (Tognon et al., 2017) (Wainwright et al., 2009) (Pompilio et al., 2015) (Ryan et al., 2008) (Pompilio et al., 2015) (Pompilio et al., 2015) (Ryan et al., 2008; Huedo et al., 2015)
<i>A. fumigatus</i>	Co-colonise the CF airway Co-colonised patients have reduced lung function Pa SNs stimulate Af growth Metacaspases from Pa SNs inhibit and damage Af biofilms ↑ elastase production by Pa in presence of Af SNs from co-cultures more toxic to epithelial cells lines Mutually antagonistic Gliotoxin produced by Af reduces Pa biofilm Co-infections cause altered inflammatory response Pa dirhamnolipids induce Af ECM production	Opportunity to interact in airway Directly associated with disease outcome Increased Af abundance in co-infections ^a Reduced Af abundance in co-infections ^a More damaging pathology More damaging pathology Competition beneficial to host? Competition beneficial to host? Evading of the immune system and persistence Inhibits Af growth ^a and facilitates Pa binding	(Armstead et al., 2014) (Reece et al., 2017) (Briard et al., 2016) (Shirazi et al., 2016) (Smith et al., 2015) (Smith et al., 2015) (Reece et al., 2018) (Reece et al., 2018) (Reece et al., 2018) (Briard et al., 2017)

^aContradictory findings.

Note: Pa = *P. aeruginosa*, Sa = *S. aureus*, Sm = *S. maltophilia*, Af = *A. fumigatus*, SNs = supernatants, EPS = exopolysaccharide, LPS = lipopolysaccharide, CFBE = cystic fibrosis bronchial epithelial cells, ECM = extracellular matrix.

Glossary

Autotroph An organism capable of synthesizing its own food from inorganic substances.

Bacterivory The ingestion of bacteria as food or as an energy supply.

Chlorophytes A group of microalgae that are coccoid or bi-flagellated, solitary or in colonies. They are green and possess chlorophylls *a* and *b* and store starch in the chloroplast. Very common in freshwater, but can also be found in marine waters.

Chloroplast Membrane-bound structure (=plastid) containing photosynthetic pigment found within a cell.

Chrysophytes A group of protists with two flagella (one short and one long) that belong to the Heterokonta. They have chloroplasts with chlorophylls *a* and *c*. They are yellowish due to carotenoids. They are common in both marine and freshwaters.

Ciliates A group of protists belonging to the Alveolata. They are characterized by the presence of hair-like organelles called cilia, which are identical in structure to eukaryotic flagella, but are in general shorter and present in much larger numbers.

Constitutive mixotrophs (CMs) Protists with built-in chloroplasts that are capable of phagotrophy.

Cryptophytes A group of protists in which most of the species contain chloroplasts with chlorophylls *a* and *c*, together with phycobili-proteins and other pigments; they vary in color (brown, red to blueish-green). Cells contain an extra reduced nucleus called a nucleomorph, which is derived evolutionarily from a previous endosymbiosis occasion.

Dinoflagellates A group of protists belonging to the Alveolata, very common in marine and freshwaters. They are bi-flagellated and possess a dinokaryon, a special nucleus characterized by the presence of a permanent nuclear envelope and chromosomes in a permanently compacted state. Half of the species lack built-in chloroplasts.

Immature successional stages A term used here to describe the colonization of pelagic waters by a few fast growing species. Immature successional stages are typically found during the spring bloom in temperate and polar regions, and upwelling areas where nutrient rich water is brought up from deep waters into the light.

Kleptoplastidy Nutritional strategy in which phototrophy is acquired by sequestration and subsequent utilization of plastids and other cell organelles from prey organisms.

Mature successional stages A term used here to describe the successional stages dominated by many slower-growing species. Mature successional stages are typically found during summer periods in temperate and polar regions, and year round in tropical open marine waters. Concentrations of inorganic nutrients are low during these stages.

Mixotroph As used here, a planktonic organism that mixes photosynthesis and food uptake via phagotrophy; sometimes referred to as a photo-phago-mixotroph.

Non-constitutive mixotrophs (NCMs) Mixotrophic protists which lack built-in chloroplasts. Some NCMs utilize ecto- or endosymbionts, while others sequester chloroplasts and sometimes other cell organelles from their prey. Species in the latter group are often referred to as klepto(chloro)plastidic.

Pelagic Describing or referring to organisms that are living in the water column in fresh and marine waters, either swimming or passively suspended; opposite to benthic (living on the bottom).

Phagotrophy Ingestion of particulate matter.

Introduction

A wide diversity of marine and freshwater unicellular eukaryotes (protists) are capable of acquiring energy, carbon and nutrients through both photosynthesis and phagotrophy of prey. Among these so-called photo-phago-mixotrophs, two major groups can be distinguished: (1) Protists with permanent, built-in chloroplasts, termed 'Constitutive mixotrophs (CMs)' (Fig. 1). These are often referred to as phytoplankton that can eat microbial prey (e.g., bacteria or other protists). (2) Protists that lack permanent chloroplasts (and often regarded as microzooplankton), but use photosynthetic machinery derived from their algal prey. These are termed, 'Non-constitutive mixotrophs (NCMs)'. Some NCMs keep the engulfed algal cells intact as ecto- or endosymbionts

Fig. 1 A panel of light and epifluorescent microscopy images showing different marine CMs. (a) *Alexandrium* sp. (ca. 45 μm in width) found in Greenland with a large food vacuole (fv), and a reduced chloroplast (chl). Photo by Hannah Blossom. (l) Confocal laser scanning micrograph image of *Prorocentrum minimum* (15–20 μm in length) fed with *Teleaulax amphioxiei*. Four food vacuoles are visible, one of which is indicated with an arrow. Modified from Johnson, M.D., 2014. Inducible mixotrophy in the dinoflagellate *Prorocentrum minimum*. *Journal of Eukaryotic Microbiology* 62, 431–443, with permission from John Wiley and Sons. (m) Five *Fragilidium subglobosum* (Fs, 40 μm) engulfing *Tripes menueri* (Tm). Adapted from Skovgaard, A., 1996. Engulfment of *Tripes* spp. (Dinophyceae) by the thecate photosynthetic dinoflagellate *Fragilidium subglobosum*. *Phycologia* 35, 490–499. All these examples are dinoflagellates except *Pymnesium parvum* (j).

(Fig. 2), while other NCMs, often termed klepto(chloro)plastidic species, retain only the chloroplasts or the chloroplasts along with prey nuclei, mitochondria, and cytoplasm (Fig. 3). Some NCMs are prey specialists and can only exploit very specific types of prey (Specialist NCM = SNCMs), while others can exploit a wide range of prey (Generalist = GNCMs).

How Common are Photo-Phago-Mixotrophic Protists in Different Aquatic Environments Compared to Photoautotrophs and Heterotrophs?

Photo-phago-mixotrophic protists are common, and often very abundant, in both freshwater and marine environments ranging from eutrophic to highly oligotrophic, and from tropical to polar. However, the relative contributions of CMs and different NCM groups to standing protist biomass and production across different scales of time and space are mostly unknown. This knowledge gap is mainly explained by the difficulty in identifying which organisms are actively mixotrophic in the field. Below we summarize current knowledge.

Fig. 2 A panel of light microscopy images showing different marine planktonic protists (NCMs) in symbiosis with microalgae, a common relationship in oceanic waters worldwide. (a,b,c) The rhizarian Radiolaria hosts symbiotic microalgal cells (yellow cells), which can be haptophytes or dinoflagellates. Radiolarians can build mineral skeletons of about 200–300 μm in size. (a) polycystines, (b) acantharians, (c) collodarians. Photos by Johan Decelle. (d) The green dinoflagellate *Noctiluca scintillans* (500–1000 μm in diameter), which can proliferate in Southeast Asia. Photo by Per Juel Hansen. (e) The rhizarian Foraminifera (*Globigerinoides sacculifer*) living with dinoflagellates (200 μm in diameter). Photo by Katsunori Kimoto. (f) The ciliate *Tiarina* sp. that builds a shell in calcium carbonate (80 μm in length) and hosts dinoflagellate symbionts (*Symbiodinium*, also found in corals) in oceanic waters. Photo by Johan Decelle. (g) The dinoflagellate *Amphisolenia* sp. that hosts pelagophyte endosymbionts along its 500 μm -long cell. Photo by John Dolan.

Fig. 3 A panel of light microscopy images showing different NCMs in marine ecosystems, which sequester the chloroplasts of their prey (kleptoplastidy). (a) The toxic dinoflagellate *Dinophysis acuta* (60 μm in length), which harbors chloroplasts of cryptophyte origin. Photo by Per Juel Hansen. (b) The ciliate *Mesodinium major* (50 μm in diameter), one of the red *Mesodinium* species. Photo by Niels Daugbjerg. (c) The oligotrich ciliate *Strombidium rassoulzadegani* (60 μm in length) with sequestered chloroplasts from different algal prey (green algae and cryptophytes). Modified from Schoener, D.M., McManus, G.B., 2012, Plastid retention, use, and replacement in a kleptoplastidic ciliate. *Aquatic Microbial Ecology* 67, 177–187, with permission from Inter-Research.

Constitutive Mixotrophs (CMs)

In principle, all eukaryotic microalgal lineages (chlorophytes, euglenophytes, cryptophytes, chrysophytes, haptophytes and dinoflagellates) have the capacity to take up prey, though it is not always present in all species of each lineage. Only diatoms are thought to lack phagotrophic capabilities as a group; but like all microalgae, they are able to utilize dissolved organic nutrients.

The major phytoplankton groups have a global distribution with smaller species present in greater proportion in oligotrophic waters, while larger species, such as dinoflagellates, will gain relative abundance in coastal waters. We can view the dominance of diatoms (autotrophs) vs CMs in an environment in the context of the supply and demand of nutrients and energy that can be fulfilled by phagotrophy. The balance between photoautotrophy and photo-phago-mixotrophy in plankton communities can be considered in significant part as determined by a combination of supply and demand of inorganic (dissolved inorganic nitrogen (DIN) and dissolved inorganic phosphorus (DIP)) and organic nutrients (including prey availability). A schematic representation of the expected seasonal progression of non-mixotrophic plankton to one dominated by mixotrophs is shown in Fig. 4.

Fig. 4 Schematic diagram of the changes to the planktonic food web over a year, with transitions between immature and mature ecosystem states. The upper panels show changing patterns of light, inorganic nutrients and particle density (i.e., total plankton biomass) over the temperate year. Transitions from mature to immature (spring or autumn "blooms") to mature again, are as indicated; green dashed line indicating conditions optimal for phototrophy, orange dashed lines for phagotrophy. Other periods are sub-optimal for strict phototrophs and/or strict phagotrophs, and preferable for mixotrophs. The lower panel shows in detail the transition from immature to mature, with changes in selection priorities from so-called "r-select" phototrophs and phagotrophs in immature ecosystems, to a mature ecosystem more optimal for "K-select" mixotrophs. Reprinted from Mitra et al., 2014. The role of mixotrophic protists in the biological carbon pump. *Biogeosciences* 11, 995–1005, with permission from Copernicus Publications.

There are two significant challenges affecting our interpretation of the role of CMs in plankton ecology. The first is the quality of plankton survey data, which usually group diverse organisms into different size classes and only identify larger cells (>20 μm) with easily recognizable morphology. Small cells are not usually sampled or identified effectively. In consequence, we know very little even in quasi qualitative terms about the global distribution of organisms that we expect to be capable of photo-phago-mixotrophy. Secondly, we do not know the extent to which these phototrophic organisms are engaging in significant levels of mixotrophy. Experimental approaches on cultured representatives are required to actually measure rates of primary production and phagotrophy, but many planktonic organisms are not in culture. Coupled to this challenge is that a degree of feeding which may not appear significant in a community ecology context, could be essential for growth if it supplies a limiting nutrient.

Non-Constitutive Mixotrophs (NCMs)

These can be found mainly among ciliates, heterotrophic dinoflagellates, foraminiferans and radiolarians. The NCMs are often relatively large cells (20–1000 μm), and some can build carbonate or silicate mineral skeletons, such as the foraminiferans and radiolarians. Despite a high dependency on photosynthesis, some NCMs need to maintain heterotrophic activity. For others, the type of prey (specificity) and the contribution of predation to the overall metabolism is still poorly understood.

Different types of NCMs inhabit different biomes (Fig. 5), though collectively they are present across the global seas. Most inhabit mature ecosystems primarily due to the distribution of their prey, which can be very specific. Examples are large symbiotic NCMs like radiolarians and foraminiferans, which are the most abundant NCMs in the surface waters of the oligotrophic open ocean. However, some NCMs that maintain symbionts or sequester prey nuclei along with the chloroplasts can inhabit waters during less mature stages. Examples of the latter are the ciliate *Mesodinium rubrum*, which is heavily influenced by upwelling, and the green dinoflagellate *Noctiluca*, which responds to eutrophication.

Feeding Mechanism, Prey Selection and Toxin Assisted Feeding

Prey Capture and Feeding Mechanisms

Suspended and motile prey can be difficult for a single-celled organism to capture and consume, but many mixotrophic protists have come up with truly spectacular ways to achieve this. Many swim and catch prey upon collision, with the prey engulfed directly into a food vacuole. Others, typically slower swimming species, have evolved various sophisticated ways of capturing prey, using a haptonema (many haptophytes), a capture filament (many dinoflagellates) or a mucus trap (some dinoflagellates). Prey are usually taken up whole by direct engulfment, but some species use a feeding tube (a type of straw) to suck out the contents, thereby enabling these mixotrophs to exploit larger prey items (Fig. 6).

Toxin-Assisted Feeding

Some mixotrophic protists use toxins to immobilize swimming prey. Examples of these include the haptophyte *Prymnesium parvum*, which releases toxins to the water to immobilize swimming prey that it would otherwise not be able to catch. Excreted toxins from the dinoflagellate *Karlodinium armiger* have been shown to be involved in capturing prey organisms that would normally be their predators, thereby reversing the food web. Excreted toxins may also be used in combination with a mucus trap, as described in the dinoflagellate *Alexandrium pseudogonyaulax* (Fig. 6), to keep effective toxin concentrations high and in close proximity. Toxin-Assisted prey capture could be more common than we realize; it may not be coincidental that most toxin producing harmful algal bloom forming species are mixotrophic.

Prey Selection

Most mixotrophic protists are thought to feed on a wide range of prey and the diet usually includes bacteria and/or other protists, but it may in some cases also include copepods and mollusc larvae. In contrast, some protists are quite selective and rely on specific species of prey. For example, the ciliate *Mesodinium rubrum* utilizes a specific clade of cryptophytes, which are incorporated into the cell body of *M. rubrum* allowing the ciliate to rely on photosynthesis as its major carbon source. In turn, *M. rubrum* is specifically consumed by *Dinophysis* spp. (dinoflagellate) in order to acquire the cryptophyte chloroplasts from the ciliate.

Abiotic and Biotic Factors Influencing Photosynthesis, Growth and Feeding Rates in CM and NCMs

Light and Prey Concentration

CMs

Most studied CMs require light for sustained growth and will not grow in complete darkness even if fed. Irradiance is required to at least fix enough carbon to match respiration needs. At higher irradiances protist growth increases until saturation, as it does with pure phototrophs such as diatoms and cyanobacteria. If prey are abundant, some CMs can grow faster mixotrophically than

Fig. 5 Global distribution of protists with acquired phototrophy (non-constitutive mixotrophs, NCMs). Functional groups identify protists which acquire plastids from a variety of prey (generalist NCMs, GNCMs; blue (a)), from specific prey (plastidic specialist NCMs, pSNCMs; red (b)), or enslave entire specific autotrophic prey (size as length): (a) GNCMs *Laboea* (100 μm) and *Strombidinium* (50 μm); (b) pSNCMs, *Mesodinium* (60 μm) and *Dinophysis* (40 μm); (c) eSNCMs, *Sphaerozoum* (200 μm) and *Noctiluca* (500 μm). On maps, symbols correspond to the exact location where mixotrophic species/taxa were found (from more than 110,000 records); the grid indicates biogeographic provinces. Color-cast provinces indicate the presence of NCMs and white provinces correspond to the absence. Provinces marked with asterisk indicate that studies conducted in these areas did not record the presence of mixotrophic species; unmarked white provinces indicate a lack of field studies providing information on acquired phototrophy among microzooplankton. Reproduced with permission from Leles et al., 2017. Oceanic protists with different forms of acquired phototrophy display contrasting biogeographies and abundance. Proceedings of the Royal Society B 284, 20170664.

phototrophically at low irradiance (e.g., *Karlodinium veneficum*) and ingestion rates increase as a function of irradiance until it also satiates (Fig. 7). In consequence, mixotrophic growth rates of CMs are often much higher than when grown purely phototrophically. There are, however, exceptions. Some species can grow in complete darkness when fed a suitable prey (e.g., some chrysophyte species of the genera *Poterioochomonas*/*Ochromonas* and the dinoflagellate *Fragilidium* spp.) and light has a very limited effect on growth and prey uptake. In other cases the growth rate increases with irradiance despite the fact that ingestion is unaffected (e.g., the dinoflagellate *Gymnodinium resplendens*).

NCMs

Most NCMs are dependent on both light and prey for sustained growth, but some species can grow completely heterotrophically in the dark if prey is available (e.g., the dinoflagellate *Noctiluca scintillans*; the ciliate *Strombidium rassoulzadegani*). Similar to CMs, the growth rates of NCMs generally increase with irradiance until saturated (e.g., *Dinophysis acuminata*; *Mesodinium rubrum*), while ingestion rates may (*Dinophysis*) or may not (*Mesodinium*) increase as a function of irradiance.

Photo by Hannah Blossom. *A. pseudogonyaulax* is approximately 35–40 μm wide.

Major and Minor Nutrients and Complex Macromolecules

Major and minor nutrients

Nutrients are essential for the growth and biochemical reactions of protists; particularly, photosynthetic activity relies on pigments and proteins that require nitrogen and metals (iron). It is generally assumed that inorganic or dissolved organic sources are the preferred source of nutrients for most microalgal groups. Thus, their availability at concentrations limiting growth is thought to promote prey ingestion in mixotrophs (Fig. 8). Indeed, many CMs appear to consume prey exclusively to obtain nutrients, maintaining photosynthesis as their primary source of carbon. However, most studies have focused on general nutrient limitation, with organisms grown in diluted growth media until limitation hampers growth, but exactly which nutrient is limiting is unknown. The few studies available focusing on limitation for specific nutrients have demonstrated that inter- and intra-species variability may occur in the mixotrophic

Fig. 7 The dinoflagellate *Karlodinium veneficum* (= *Gyrodinium galathecium*). (a) Growth rate as a function of irradiance. *K. veneficum* was grown phototrophically in mono-specific cultures (circles) and mixotrophically in cultures with daily addition of cryptophyte prey *Storeatula major* (triangulars). (b) Ingestion rate of *K. veneficum* in food-saturated cultures as a function of irradiance. Error bars indicate ± 1 SE, $n=3$. PFD: photon flux density. Adapted from Li et al., 1999. Feeding, pigmentation, photosynthesis and growth of the mixotrophic dinoflagellate *Gyrodinium galathecium*. Aquatic Microbial Ecology 19, 163–176, with permission ©Inter-Research 1999.

response when limited for different nutrients. As both major (nitrogen and phosphorous) and minor (e.g., iron) nutrients are known to be important factors constraining planktonic primary production, the lack of clarity on interactions between inorganic nutrient stress and predation severely hampers our understanding of CM ecology. Nutrient uptake in NCMs is largely unexplored. However, uptake of inorganic and dissolved major nutrients has been shown recently in *Dinophysis* spp. and *Mesodinium rubrum*.

Complex macromolecules

Many CMs are known to be auxotrophic for complex vitamins, amino acids and fatty acids, due to the loss or absence of part or all of the genes required for synthesis. This phenomenon is so prevalent that certain vitamins, such as B_{12} , are routinely added to isolation and growth media to ensure microalgal growth. Paradoxically, very few studies have assessed the influence of complex macromolecules on feeding. For example, the haptophyte *Prymnesium parvum* has been shown to take up fatty acids from phagocytized ciliate and bacterial prey and is thought to use them as building blocks for membrane biosynthesis.

New Techniques in the Study of Mixotrophs to Assess Feeding and Nutrient Uptake

Omics

During the last decade, the application of omics techniques has revolutionized microbial oceanography. Detailed genome information is necessary to understand the evolutionary history of protists and important events in eukaryotic evolution such as lateral or horizontal gene transfer. Many groups of aquatic protists still have no, or only very few, genomes sequenced. The data available indicate that phagotrophy and photosynthesis occur in most major lineages, thus the capacity for mixotrophy among many aquatic protists would be an ancestral adaptation/capacity.

Fig. 8 The dinoflagellate *Tripos furca* (= *Ceratium furca*). Ingestion rates of cultures compared to inorganic phosphorus (PO_4) and nitrogen ($\text{NO}_2 + \text{NO}_3$ and NH_4) concentrations over time. (a) f/2-P medium, (b) f/2-N medium. Data are presented as mean $\pm$ SE. Reproduced from Smalley et al., 2003. Feeding in the mixotrophic dinoflagellate *Ceratium furca* is influenced by intracellular nutrient concentrations. Transcriptomics is the analysis of gene expression. In this method, RNA is extracted from single cells or cultures and sequenced. As RNA is the messenger of genetic information from the nucleus to the cytoplasm of the cell, the sequenced RNA gives an overview over which genes are expressed at a certain point in time within single cells. This can improve our understanding of cell physiology, particularly how they respond to different environmental constraints. Using this method it was found that the availability of light has a minimal effect on population growth of the CM, *Ochromonas* sp. (chrysophyte). An upregulation of phototrophy- and phagotrophy-related genes was observed, while the availability of bacteria as prey led to major changes in carbon and nitrogen metabolic pathways. Further, transcriptomics of *Prymnesium parvum* showed that bacteria and ciliate prey were sources of organic carbon, macro- and micro-nutrients, organic nitrogen, and fatty acids. However, a large part of expressed genes in transcriptomes typically remains unassigned to a specific function, thus preventing a full understanding of physiological mechanisms.

High Resolution Chemical Imaging (NanoSIMS: Nanoscale Secondary Ion Mass Spectrometry)

Based on cell lysis and extraction of molecules, omics data only provide averaged information from cell population and their organelles. This is an especially important consideration in the study of interactions between heterotrophs and their algal symbionts or between heterotrophs and their sequestered chloroplasts, since it is generally difficult to identify the origin of a gene function/metabolite, and to distinguish the role of each partner and/or organelles. Thus, intra-cell spatial information is needed to further decipher the complex nutritional strategies of mixotrophs.

Recent advances in high-resolution single-cell chemical imaging coupled with stable isotopes now allow the observation and quantification of the metabolic activity within a single cell. In particular, nanoscale mass spectrometry imaging (nanoSIMS) is one of the most powerful chemical imaging platforms, available to biologists, with high mass and high spatial resolution capabilities (<100 nm) and excellent sensitivity (detection limit in the ppm or ppb range). NanoSIMS can document metabolic transfers between closely interacting cells and organelles, as well as the subcellular distribution of major nutrients (N, P and N, P and S) and metals. More specifically, following isotope incubation with ^{13}C or ^{15}N , nanoSIMS can elucidate the incorporation and flux of the isotope in cells at the subcellular level. This can be used to characterize and quantify the nutritional exchange between symbiotic partners, but also to quantify the contributions of photosynthesis and heterotrophy to the metabolism and growth of mixotrophs. As an example, nanoSIMS demonstrated that the chrysophyte *Ochromonas* sp. predominantly acquires carbon and nitrogen from bacterial prey when available, whereas inorganic C and N is assimilated primarily when bacterial

abundance is low. This technique should be applicable for determining the relative role of phagotrophy and photosynthesis in both CMs and NCMs over a range of conditions.

Measurements of “In Situ” Feeding Rates in Mixotrophs: Variation in Time and Space (Seasonality, Vertical and Diel Variations)

Experiments on cultured organisms are required to understand the ecology and physiology of aquatic protists. However, scaling results of these microcosm experiments to large-scale natural systems is challenging for a number of reasons: (i) In contrast to simplified and strictly controlled cultures, natural ecosystems are immensely complex, with protist behavior influenced by interacting and fluctuating factors. (ii) Some external drivers for protist behavior, such as small scale turbulence, are very difficult to mimic under laboratory conditions. (iii) Isolation and culturing selects for species that survive under standard culture conditions, but these do not necessarily represent the most important species in the field. (iv) Culture studies tend to be with single strains or species within a genus, potentially ignoring significant inter-strain and inter-species variability. To understand the dynamics of mixotrophic protists in aquatic systems, culture studies need to be complemented by *in situ* studies. Field studies provide generalized patterns of how natural communities respond to environmental shifts; while culture studies help us understand these patterns by concentrating on selected populations subjected to specific environmental cues.

Bacterivorous CMs and NCMs

Bacterivory rates in mixotrophs are most commonly measured by tracking the ingestion of fluorescently labeled bacteria (FLB). The assumption behind this technique is that mixotrophs feed indiscriminately, ingesting FLB at the same rate as co-occurring natural bacteria. This technique is relatively simple, with the possibility to target specific protist groups based on pigment signatures or gene probes. However, it has some caveats: (i) Not all mixotrophs feed indiscriminately, and selection for or against the FLB can occur, leading to biased results. (ii) Bacterivory rates can fall below detection limits when feeding rates are low. (iii) It is laborious and time-consuming. Alternative methods exist, but they present their own limitations, making the development of more accurate methods to determine mixotrophic bacterivory a major goal for future studies. As an example, food vacuole markers, such as acidotropic probes, can be used to determine the fraction of feeding cells in a population. This method is fast and highly sensitive, but cannot provide feeding rates since the number of ingested bacteria is unknown.

Despite these complications bacterivory by mixotrophs, primarily CMs, has been generally shown to account for 30%–60% of bacterial consumption in diverse freshwater and marine systems. Mixotrophic bacterivory can thus equal or surpass that of heterotrophic protists, the organisms previously held as the principal cause of bacterial mortality, along with viral lysis. The principal bacterivorous mixotrophs are small (2–10 μm diameter) phytoflagellates of diverse phylogeny. Haptophytes and chrysophytes are well established as major bacterivores, but there are increasing indications that cryptophytes and chlorophytes could also play a significant role. Most information available is extrapolated from punctual studies, with very few assessments existing of bacterivory along spatial and temporal scales. The relative importance and regulation of bacterivory by different algal groups and the spatio-temporal variability of bacterivory are major fields for future study, and vital information for correctly incorporating these organisms into the models that predict productivity of aquatic systems.

CMs and NCMs That Feed on Other Protists

Current methods fall short in measuring general *in situ* feeding rates of CMs and NCMs that feed on other protists, due to the much wider range of prey and predator sizes and the enormous differences in prey motility. Fluorescently labeled protistan prey can be used, but only to measure grazing rates of specific mixotrophs on very specific prey. This has been done to estimate grazing of *Tripod furca* (dinoflagellate CM) on small ciliates and of *M. rubrum* (ciliate NCM) on specific cryptophytes. However, this technique is not very useful for estimating the grazing rates of mixotrophs that ingest a variety of protistan prey, for example many of the CM dinoflagellates, plastid retaining oligotrich ciliates (NCMs), and mixotrophic foraminiferans and radiolarians (NCMs). Thus, a major future challenge is the development of methods to measure *in situ* feeding rates of these protists.

Incorporation of Mixotrophs in Food Web and Biogeochemical Models – Challenges for the Future

Models for support of fisheries, harmful algal bloom science, and biogeochemistry are based almost exclusively on the traditional paradigm of nutrient-phytoplankton-zooplankton (i.e., NPZ) with links to higher trophic levels. Having established that the bulk of the “phytoplankton” and half the “microzooplankton” (which as a collective form ca. 60% of “zooplankton”) are photo-phago-mixotrophs, radically alters the conceptual framework for such simulation models. In theory, the “phytoplankton” are no longer simply restrained by nutrients and light, and the “microzooplankton” are less likely to starve. Mixotrophy has long provided a basis for explorations of trait-trade-offs in theoretical ecology. However, mixotrophs in such models have almost exclusively been configured as CMs, often including trade-offs that have not been substantiated by physiology studies. If such trade-offs are not

implemented, then modelled mixotrophs come to dominate; ironically, as we now better understand their physiology and ecology, that is indeed sometimes true.

Models including mixotrophs typically fail to describe the variety of mixotrophic formats and the relative roles of different nutritional modes operating under different conditions. This situation, in part, reflects the lack of data and understanding of mixotroph physiology, and also of their prey that concurrently inhabit the environment. This lack of understanding has led some to propose conceptual frameworks for plankton ecosystem modelling. One framework is based on scaling laws which indicates an allometric scaling for osmotrophy (bacteria), phototrophy (phytoplankton), mixotrophy and then particle feeding (zooplankton). The fallacy of the argument is revealed by the fact that some of the very smallest protist “phytoplankton”, as exemplified by *Micromonas*, are mixotrophic. At the other extreme there are mixotrophs (foraminiferans, radiolarians, green *Noctiluca*) that are amongst the largest single celled organisms, and are larger than many metazoan zooplankton. We now know that mixotrophy is important in planktonic ecosystems and there is a drive for better marine ecosystem models for climate change prediction. However, we lack the physiological understanding and numeric data to properly construct and constrain simulation models. To get to where we need to be will take a significant and coordinated effort.

For field work we need survey protocols that adequately and routinely sample the plankton down to 2 μm . We also need experimental protocols that can provide data on the contributions of phototrophy and phagotrophy in different organism groups. How molecular biology can contribute to our understanding in the quantitative way required to support modelling is at present unclear. An allied issue is that molecular biology provides high resolution details down to sub-species or individual cell level, while models have to clump organisms together as functional groups. It is not yet clear how best to build those functional groups.

Laboratory experiments have significant potential to aid model construction, at least of the few species that are cultured. Notably such work requires simultaneous studies of both prey and mixotrophs growing alone, and together, with time series analysis of changes in nutrients, biomass, C:N:P and pigments. Fully integrated physiological-molecular-modelling studies likely offer the best route to enhancing conceptual, practical and numeric understanding; modelling efforts need to be fully embedded in the research effort and not left to the end. What we do have is sufficient conceptual understanding to build alternative structures, models that can be switched to better represent different physiological strategies, and that can be used to test against experimental data and to help us better interpret those data. Thus the “perfect beast” model, which is a simulation model (Fig. 9) has been used variously to explore CMs and NCMs in experimental, field and conceptual scenarios. Integrating molecular biology in such laboratory studies

Fig. 9 Conceptual models for the four main photo-phago-mixotrophs. Constitutive mixotroph (CMs) contain their own innate ability to synthesize photosynthetic machinery, use inorganic nutrients, and eat prey. Non-constitutive mixotrophs (NCM) do not possess an innate ability to do photosynthesis but must acquire the ability; they follow three patterns. The generalists (GNCM) can exploit photosystems from many prey types but have little ability to maintain and control them. Plastidic specialists (pSNCM) acquire plastids and some allied nucleic material from very few prey species (though they can eat many prey types); they can achieve a much enhanced level of phototrophy maintenance and control compared to GNCMs. The endosymbiotic specialists (eSNCM) contain fully functional phototrophic algae; they operate in a way akin to a floating greenhouse. Of these, the “perfect beast” model of Flynn and Mitra (2009) can describe all but the eSNCM format. DIM – dissolved inorganic matter (nutrients); DOM – dissolved organic matter. Reproduced from Flynn, K.J., Mitra, A., 2012. Building the “perfect beast”: Modelling mixotrophic plankton. *Journal of Plankton Research* 31, 965–992, with copyright permission from Oxford Academic.

would also help ground omics approaches, providing the missing links between RNA transcripts and function mentioned above. This would, in turn, improve the linkage between field studies and models which is essential for building robust simulation platforms.

What we can say for sure is that the complexity of the control of physiology within a given species (responses to light, nutrients, prey etc.), and differences in physiology between different mixotroph groups, argue strongly against attempts to deploy simple descriptions. Indeed, outputs from such models should likely be viewed with as much skepticism as we would now view simple NPZ models given what we now know about the role of mixotrophy in aquatic ecology.

Introduction

The term *microorganism* or *microbe* refers to all unicellular organisms, which are microscopic in size ($<1000\ \mu\text{m}$), including prokaryotes (bacteria and archaea) and unicellular eukaryotes (protists). Microbes are possibly the earliest evidence of life on Earth, approximately 3.700 million years ago (Dodd et al., 2017). Today, the vast majority of microbial prokaryotes (bacteria and archaea) on Earth are found in the open ocean (10^{29} cells), soils (10^{29} cells), deep oceanic and terrestrial subsurfaces (10^{30} cells). Bacteria are the largest contributor to global microbial biomass, followed by archaea, protists, and unicellular eukaryotes (Bar-On et al., 2018). The global biomass of bacteria on Earth is estimated to be 70 Gt Carbon, which constitutes 15% of global carbon biomass of all living organisms on Earth. This figure is dominated by terrestrial deep subsurface environments (60 Gt C) and marine deep subsurface environments (9 Gt C). The global biomass of archaea is estimated to be 7 Gt C, a figure dominated by terrestrial (4 Gt C) and marine deep subsurface (3 Gt C) environments. In open ocean environments, for instance, the abundance of bacteria is four times the abundance of archaeal cells (Bar-On et al., 2018), and the entire microbial food web, including protozoan microzooplankton, is generally from five to ten times the mass of all multicellular marine organisms (Pomeroy et al., 2007). The human gut is also a large reservoir of microbial prokaryotes, with the number of bacterial cells residing in the human body being of the same order as the number of human cells (i.e., close to a 1:1 ratio) (Sender et al., 2016), although is not as species rich (on the order of 10^2 bacterial ecotypes) compared to soils or oceans (Faith et al., 2013). Freshwater microbial eukaryotic richness is estimated to be on the order of $2 \cdot 10^4$ species (Debroas et al., 2017).

Microbes can live as single-cells or form colonies. In addition to their ubiquity and important contribution to the global pool of carbon, microorganisms play fundamental roles in several biochemical processes and their ecological importance is, nowadays, unquestionable (Prosser et al., 2007b). Marine microbial communities are at the bottom of the trophic food webs that ultimately feed global fisheries, and about one half of Earth's primary production occurs in the ocean (Field et al., 1998). Microbes control many processes that sustain life on Earth: they are crucial for virtually all biogeochemical processes, perform photosynthesis, and decompose inert organic matter into simpler compounds that are the basis of many food chains (Falkowski et al., 2008; Thompson et al., 2017). Moreover, they frequently constitute the basis of food webs themselves, both in marine and terrestrial ecosystems (Field et al., 1998). Microbial communities often live in association with host organisms, both plants and animals, including humans, where they have a very profound impact in controlling host's health and several aspects of their life cycles, such as flowering time in plants or reproductive behavior in animals (Leitão-Gonçalves et al., 2017; Wagner et al., 2014). From a biotechnological perspective, microorganism consortia are used to purify wastewater, control catalytic reactions, including those involved with biofuels, and increase crop yields (Halan et al., 2012; Mueller and Sachs, 2015). Finally, even though most microbes are harmless, some species are responsible of diseases that affect multicellular organisms, including humans (Costerton et al., 1999).

The aim of this article is to provide a summary of the state-of-the-art regarding the use of mathematical models in microbial ecology and plankton dynamics. Unveiling the means by which microbial communities assemble, stabilize, and operate is essential to predicting and manipulating their functions, and thus likely to be among the most important questions modern ecology faces. Such relevance arises not only from the intellectual merit of the question *per se*, but also from its utility for coping with many of the challenges that will confront human society in the coming years, such as the management of natural resources and ecosystems or the palliation of the effects of climate change (Prosser et al., 2007a). Despite this well-founded importance, there are large gaps of knowledge about the rules governing the assembly of microbial communities. Such gaps partly stem from the difficulty of studying microbes in their natural ecological context, which has biased the development of microbiology towards studies in which populations are treated in lab-created setups that do not capture the complexities of the natural environments. In this scenario, the development of ecological models, as shown in this article, and recent experimental efforts aiming to quantify species interactions in increasingly complex communities, can improve our understanding of how microbial communities operate and affect ecosystem functioning.

Uptake Machinery

One of the main ways in which microbes interact with their environment is through their uptake machineries, which enable the harvesting of key resources that they require to grow. Autotrophic microbes, for example, harvest sunlight through their photosynthetic apparatus. Both autotrophs and heterotrophs capture key inorganic and/or organic nutrients using membrane transport

proteins, also called transporters (see Fig. 1) (Caperon, 1967). Models have considered uptake machineries in many different ways. The uptake of light by autotrophic microbes, for example, was initially approached simply as if it were one more nutrient (Jassby and Platt, 1976), although current models take into account the dynamics of cellular chlorophyll and the photosynthesis apparatus (Cullen, 1990). The classical representation for nutrient uptake, on the other hand, centers on the “Michaelis-Menten” (MM) functional form (Michaelis and Menten, 1913). This equation is based on theoretical considerations (see chapter “Enzyme Kinetics” of Lehninger’s book (Nelson et al., 2008)) and has been supported by empirical observations leading to the “Monod model” of microbial growth (Monod, 1949).

If we call $U(R)$ to the uptake rate ($\text{mmol cell}^{-1} \text{ day}^{-1}$) for a particular nutrient or resource R (mmol m^{-3}), the *canonical* MM equation is usually written as:

$$U(R) = \frac{U_{\max} R}{(U_{\max}/A) + R} = \frac{U_{\max} R}{K_R + R} \quad (1)$$

where $U_{\max}$ represents the maximum possible uptake rate ($\text{mmol cell}^{-1} \text{ day}^{-1}$) of the cell; and A is the nutrient uptake affinity ($\text{m}^3 \text{ cell}^{-1} \text{ day}^{-1}$) of the cell. The ratio $K_R = U_{\max}/A$ is called the half-saturation constant (mmol m^{-3}) because it represents the concentration of resources at which the uptake rate is half of its maximum ($U_{\max}/2$). See Box 1 for a step-by-step derivation of the MM equation and its use in resource uptake kinetics. See also Aksnes and Egge (1991), Bonachela et al. (2011), Nelson et al. (2008) and Vallina et al. (2014b) for alternative derivations of the MM equation.

Sometimes it may be convenient to use instead biomass-normalized traits by defining $\alpha_p = A B^{-1}$ as the specific uptake affinity ($\text{m}^3 \text{ mmol}^{-1} \text{ day}^{-1}$) and $\rho_{\max} = U_{\max} B^{-1}$ as the specific maximum uptake rate (day^{-1}), where B is the cell’s biomass (mmol cell^{-1}).

Box 1 Michaelis-Menten kinetics

- Enzyme-substrate reaction

The canonical Michaelis-Menten equation was originally derived to describe enzyme-substrate kinetics (Briggs and Haldane, 1925; Michaelis and Menten, 1913). The MM equation describes the formation of a product (P) from a substrate (S), mediated by the binding interaction with an enzyme (E) to form a complex enzyme-substrate (ES) that finally releases the product. This two-step sequence of reactions (binding + catalysis) can be described by the following diagram:

where [S] is the concentration (mmol m⁻³) of substrate; [E] is the concentration (mmol m⁻³) of free enzymes; [ES] is the concentration (mmol m⁻³) of enzymes forming the enzyme-substrate complex (*i.e.*, non-free enzymes); [P] is the concentration (mmol m⁻³) of the product; k_a is the forward reaction rate constant (m³ mmol⁻¹ d⁻¹) to form complex ES; k_h is the forward dissociation rate constant (mmol mmol⁻¹ d⁻¹) of complex ES to form product P; and k_d is the reverse dissociation rate constant (mmol mmol⁻¹ d⁻¹) of complex ES back to free enzymes and substrate.

The law of mass action enables writing the reactions as a set of differential equations:

$$\frac{d[S]}{dt} = -F_a + F_d \quad (5)$$

$$\frac{d[E]}{dt} = -F_a + F_h + F_d \quad (6)$$

$$\frac{d[ES]}{dt} = F_a - F_h - F_d \quad (7)$$

$$\frac{d[P]}{dt} = F_h \quad (8)$$

$$F_a = k_a[E][S] \quad (9)$$

$$F_h = k_h[ES] \quad (10)$$

$$F_d = k_d[ES] \quad (11)$$

where F_i represents the fluxes (mmol m⁻³ d⁻¹) among state-variables in the system, each of them governed by a rate constant k_i (see arrows in Eq. (4)). The MM kinetics assumes a single binding site per enzyme, thus 1 mole of enzyme binds to 1 mole of substrate to form 1 mole of enzyme-substrate complex. The total concentration of enzymes $[E_T]$ is assumed to be constant (*i.e.*, conservation constrain) and is given by the sum of the free enzymes [E] plus the non-free enzymes forming the complex [ES]:

$$[E_T] = [E] + [ES] \quad (12)$$

Assuming steady-state of the complex [ES], solve for [E] using Eq. (7):

$$F_a = F_h + F_d \quad (13)$$

$$[E][S] k_a = [ES](k_h + k_d) \quad (14)$$

$$\frac{[E][S]}{[ES]} = \frac{k_h + k_d}{k_a} \equiv k_m \quad (15)$$

$$[E] = k_m \frac{[ES]}{[S]} \quad (16)$$

where the parameter k_m is known as the Michaelis constant (mmol m⁻³), a.k.a. half-saturation constant.

Substituting Eq. (16) into Eq. (12) and solving for [ES]:

$$[E_T] = k_m \frac{[ES]}{[S]} + [ES] = \frac{k_m + [S]}{[S]} [ES] \quad (17)$$

(Continued)

Box 1 (Continued)

$$[ES] = [E_T] \frac{[S]}{k_m + [S]} = \frac{[E_T][S]}{((k_h + k_d)/k_a) + [S]} \quad (18)$$

Substituting Eq. (18) into Eq. (8) and solving for the production rate of P:

$$V(S) \equiv \frac{d[P]}{dt} = \frac{k_h [E_T][S]}{((k_h + k_d)/k_a) + [S]} \quad (19)$$

The maximum production rate ($\text{mmol m}^{-3} \text{d}^{-1}$) occurs when all enzymes are tied to a substrate (*i.e.*, saturating conditions), which means that there are no free enzymes ($[E] = 0$) since they are all bound as enzyme-substrate complex ($[ES] = [E_T]$). Thus:

$$V_{\max} = k_h [E_T] \quad (20)$$

Substituting Eq. (20) into Eq. (19) we obtain the final expression for the production rate V ($\text{mmol m}^{-3} \text{d}^{-1}$) of product P from substrate S:

$$\begin{aligned} V(S) &= \frac{k_h [E_T][S]}{((k_h + k_d)/k_a) + [S]} \\ &= \frac{V_{\max}[S]}{k_m + [S]} \end{aligned} \quad (21)$$

- Resource uptake analogy

By direct analogy, we can translate the canonical MM equation to model the uptake rate of resources by microbes using the following change of variables:

$$[S] = [R] \quad (22)$$

$$[E_T] = n [N] \quad (23)$$

$$k_a = a \quad (24)$$

$$k_h = h \quad (25)$$

$$k_d \ll k_h \quad (26)$$

$$k_m = K_R \quad (27)$$

where $[R]$ is the molar concentration of resource (mmol m^{-3}); $[N]$ is the abundance of microbes (cells m^{-3}) in the population; n is the number of transporters per cell (sites cell^{-1}); a is the binding affinity per transporter ($\text{m}^3 \text{site}^{-1} \text{d}^{-1}$) for the resource; and h is the handling rate per transporter ($\text{mmol site}^{-1} \text{d}^{-1}$) for the resource. Substituting Eqs. (24)–(29) into Eq. (21) gives the uptake rate of resource by the microbial population ($\text{mmol m}^{-3} \text{d}^{-1}$)

$$V(R) = \frac{h n [N][R]}{(h/a) + [R]} \quad (28)$$

Dividing equation Eq. (28) by the biomass concentration (mmol m^{-3}) of the microbial population $[C] = B \times [N]$, where B is the biomass per cell (mmol cell^{-1}), then leads to the MM equation for specific uptake rate (d^{-1}) of resource R by the microbial population, which was also previously defined in the main text (see Eq. (2)):

$$\begin{aligned} \rho(R) &\equiv \frac{V(R)}{[C]} = \frac{h n B^{-1} [R]}{(h/a) + [R]} \\ &= \frac{\rho_{\max} [R]}{K_R + [R]} \end{aligned} \quad (29)$$

Thus, if we call $\rho(R)$ to the biomass-specific uptake rate (day^{-1}) for resource R (mmol m^{-3}), the *biomass-specific* MM equation becomes:

$$\begin{aligned}\rho(R) &= \frac{\rho_{\max} R}{(\rho_{\max}/\alpha_{\rho}) + R} \\ &= \frac{\rho_{\max} R}{K_R + R}\end{aligned}\quad (2)$$

The Michaelis-Menten model for resource acquisition described in Eq. (2) effectively summarizes the main features of the nutrient uptake apparatus using just two primary traits: specific affinity α_{ρ} and specific maximum uptake rate $\rho_{\max}$. Graphically, the specific affinity α_{ρ} represents the initial slope of the curve that relates the specific uptake rate $\rho(R)$ to the external concentration of resources (Button et al., 2004), while the specific maximum uptake rate $\rho_{\max}$ represents the horizontal asymptote of the uptake curve that is reached at infinite resource concentration (see Fig. 2). Ecologically, the specific affinity quantifies the competitive ability of microbes at low resource concentration, and the specific maximum uptake rate quantifies the competitive ability of microbes at high resource concentration. Formally speaking, the half-saturation constant is a composite trait of these two primary traits ($K_R = \rho_{\max}/\alpha_{\rho}$). Extensions of Eq. (2) can be used to model the uptake of several substitutable forms of the same elemental nutrient (e.g., nitrate, nitrite, and ammonium forms of nitrogen), and can be combined with other expressions (e.g., Liebig's law of the minimum (de Baar, 1994)) to model the uptake of several non-substitutable nutrients (e.g., phosphorous, nitrogen, iron, etc).

The specific Michaelis-Menten equation for resource uptake can also be expressed as a function of the number n of transporters specific to the focal nutrient (sites cell^{-1}); the handling h rate of the nutrient ions per transporter ($\text{mmol site}^{-1} \text{day}^{-1}$); and the affinity a constant per transporter ($\text{m}^3 \text{site}^{-1} \text{day}^{-1}$), which results from considering the area of the transporter ($\text{m}^2 \text{site}^{-1}$) times its mass transfer efficiency (m day^{-1}) for the nutrient. Let's now define $\rho_{\max} = n h B^{-1}$, $\alpha_{\rho} = n a B^{-1}$, and $K_R = (\rho_{\max}/\alpha_{\rho}) = (h/a)$, where B is the biomass of the cell (mmol cell^{-1}). That represents the MM uptake rate as a function of three major physiological traits of the cell, normalized by its biomass (B), providing further biological context to the MM uptake kinetics parameters. Then Eq. (2) becomes:

$$\begin{aligned}\rho(R) &= \frac{(h n B^{-1}) R}{(h/a) + R} \\ &= \frac{(h n B^{-1}) R}{K_R + R}\end{aligned}\quad (3)$$

Variations of Eq. (3) have been used to model the uptake of several nutrients by different transporters (see Section "Elemental Stoichiometry") or even the uptake of the same nutrient by several types of transporter (Button, 1998). Furthermore, Eq. (3) can be used to relate a "gleaner – opportunist" trade-off to the three physiological traits that the cell can manipulate (number of

Fig. 2 Michaelis-Menten function (gray dots) that relates the specific uptake rate $\rho(R)$ (day^{-1}) to the external concentration of resources (mmol m^{-3}). The specific affinity α_{ρ} ($\text{m}^3 \text{mmol}^{-1} \text{day}^{-1}$) represents the initial slope of the curve at zero resource concentration (white dots). The specific maximum uptake rate $\rho_{\max}$ (day^{-1}) represents the horizontal asymptote (black dots) of the curve that is reached at infinite resource concentration. The lines for specific affinity and maximum uptake rate intersect at the half-saturation constant K_R . The specific affinity quantifies the competitive ability of microbes at low resource concentration, and specific maximum uptake rate quantifies the competitive ability of microbes at high resource concentration. Formally speaking, the specific affinity and specific maximum uptake rate are primary traits, while the half-saturation constant is a composite trait of these two primary traits ($K_R = \rho_{\max}/\alpha_{\rho}$).

transporters, their affinity, and their handling rate) by imposing that $\alpha_p \times \rho_{max} = (n/B)^2 (h/a) = \text{constant}$. See Section “Functional Trade-Offs” for more details.

The examples above, however, neglect the possibility for the cell to regulate the uptake apparatuses as a response to changes in the environment. This phenotypic plasticity has been documented in the past in a diversity of microbes and for a wide range of resources, including light as well as nutrients (Smith et al., 2009). Because they affect microbial growth, understanding these acclimation responses is essential to predicting reliably the role of microbes in ecosystem functioning (e.g., global biogeochemistry). In the case of light acclimation, modelled responses range from changes in pigments that optimize light uptake to photo-protective mechanisms limiting damages caused by excess of light to the photosynthetic apparatus (Armstrong, 2006; Geider et al., 1998; Litchman and Klausmeier, 2008). In the case of nutrient uptake, cells can for example alter the number and handling rate of transporters used to take up the focal nutrient. Most models focus on the commonly observed negative correlation between nutrient availability and maximum uptake rate ρ_{max} by means of phenomenological expressions (Morel, 1987). More mechanistic models include interactions between different eco-physiological processes and cellular nutrient pools by assuming instantaneous acclimation time (Geider et al., 1998; Pahlow and Oschlies, 2009; Smith et al., 2009), or including explicitly a dynamic equation for transporter regulation (Bonachela et al., 2013; Bonachela et al., 2011). Such models have been employed to reproduce successfully laboratory and field patterns that were not explained by non-plastic models (Arteaga et al., 2016; Lomas et al., 2014; Smith et al., 2015). Including a dynamic number of transporters allows equation Eq. (3) to account for another important feature that this MM equations neglect: the so-called boundary layer for the cell (see Bonachela et al., 2011 and references therein for details). Mixing high- and low-affinity transport systems, where at least one system is inducible (i.e., whose expression is genetically regulated), is an alternative way of implementing plasticity of nutrient uptake. Under nutrient-replete conditions, there is a low affinity transporter that is always expressed; but under nutrient starvation, the synthesis of a high affinity transporter is switched on. This leads to a varying mix of two different uptake curves, in different proportions depending on the numbers of each transporter type (Lin et al., 2016). However, phenomenologically this mix of the high and low affinity transporters can look like a single Michaelis-Menten uptake curve with phenotypic plasticity. Because in some well studied cases the genes of these regulatory systems are known (Martiny et al., 2006), this opens the venue for linking mechanistic modelling of uptake kinetics to ecological and evolutionary processes of microbes (see Sections “Ecological Selection and Community Assembly” and “Ecological Evolution and Community Adaptation”).

Although more experimental information is becoming available, our understanding of the wide diversity of microbial acclimation processes remains limited. One aspect that remains unknown, for example, is the metabolic cost of plasticity in the uptake apparatus which, as models have shown, potentially plays an important role in whether responding to environmental changes is beneficial or detrimental to the microbial organism (Menge et al., 2011); also, the evolutionary cost and trade-offs that emerge from the use of, e.g., the nutrient uptake apparatus as a gateway for viral infections by bacterio- and phyto-phages (Menge and Weitz, 2009). Finally, more and more models are now exploring the eco-evolutionary interactions that emerge from the overlap between acclimation in the uptake apparatus and microbial rapid evolution (Kremer and Klausmeier, 2013; Lomas et al., 2014), interactions that are key to predict reliably microbial dynamics and their role in their environment.

Elemental Stoichiometry

Understanding microbial elemental composition is essential to understanding the role that microbes play in local and global biogeochemistry (Bonachela et al., 2016; Geider and La Roche, 2002). Microbes require a wide range of micro- and macro-nutrients to grow and reproduce. Models for microbial growth typically rely on the Liebig's law of the minimum and focus only on the nutrient that limits most such growth (de Baar, 1994). However, the identity of this nutrient is highly species- and environment-specific. For example, whereas carbon is typically considered the limiting resource for bacteria such as *Escherichia coli* in terrestrial ecosystems, phosphorus typically limits microbes in fresh water, and nitrogen is limiting in marine environments (Moore et al., 2013; Proctor and Karl, 2007; Sterner and Elser, 2002). Iron is essential for all autotrophic microbes, whereas silica is only limiting for diatoms. Furthermore, in the absence of other mechanisms or competitive interactions, the number of elemental nutrients (i.e., that cannot be substituted one for another) imposes an upper limit in the number of microbial populations that can coexist at equilibrium in a single homogeneous habitat. In other words, the maximum number of microbial ecotypes coexisting at steady-state cannot exceed the number of essential resources, in the absence of environmental heterogeneity (either spatial and/or temporal) and/or stabilizing interactions (Grover, 1997) (see Section “Food Web Dynamics”).

Based on the observation that several parts of the ocean show a remarkably constant ratio of key nutrients such as carbon, nitrogen, and phosphorus (Redfield, 1934, 1958), models have classically approached microbial elemental composition by focusing on the most limiting nutrient and calculating cell content and uptake of the rest of nutrients using the so-called Redfield ratios. Such approach has been used in aquatic ecosystem models, both at the local and the global level (e.g., Follows et al., 2007). However, more recent theoretical and field observations have shown that microbial elemental ratios are highly variable in the short and long term (Galbraith and Martiny, 2015), and that different microbial species manage such ratios in different ways in response to their environment (Klausmeier et al., 2004a; Martiny et al., 2013). Early models introduced the possibility of a dynamic ratio of, e.g., nitrogen to phosphorus assuming total independence between the two (Klausmeier et al., 2004b; Legovic and Cruzado, 1997; Smith and Yamanaka, 2007). Cells in these models show limitation by either one or the other nutrient, which provides arguments for coexistence between species that, for the same environmental conditions, are limited by different nutrients. Under this situation,

a sufficient condition of stable coexistence is that each microbial ecotype must be a stronger competitor for the nutrient limiting its own growth than for the nutrients limiting its competitors' growth (Grover, 1997; Tilman, 1982). Except for extreme conditions such as high mortality rates, in these models the cellular elemental ratio matches that of the nutrients introduced in the environment, which is an homeostatic response that has been observed experimentally (e.g., Rhee, 1978). These models also replicate early laboratory observations regarding the existence of one single input ratio for which growth is limited by the two nutrients, which represents an optimum as it is the point with the least limitation by either resource (Rhee and Gotham, 1980).

For microbes, however, nutrients such as phosphorus and nitrogen are not completely independent from each other; for example, phosphorus is essential for protein synthesis (e.g., in the form of ATP), and proteins are mostly composed of nitrogen (Geider and La Roche, 2002). Models that have introduced interactions between the different cellular nutrient pools predict a much wider set of environmental conditions for which co-limitation is possible (Agren, 2004; Arteaga et al., 2016; Bonachela et al., 2013; Klausmeier et al., 2007; Pahlow and Oschlies, 2009). As a consequence, the patterns of coexistence predicted by these more realistic models change significantly with respect to those of early models, which in turn affects their predictions regarding microbial community composition. Modelling such nutrient interactions is, nonetheless, a highly non-trivial task due to the multiple layers at which they occur and how the dynamics of microbial stoichiometry are intertwined with other resources (e.g., light, temperature (Moreno et al., 2018)) or cellular plastic responses to resource changes (e.g., regulation of nutrient uptake proteins; see Section "Uptake Machinery"). For the same reasons, essential aspects of such dynamics and their overall emergent results remain unknown. For example, the extent to which the correlation between microbial maximum growth rate and phosphorus content (the so-called growth rate hypothesis (Elser et al., 1996)) holds across organisms and different environmental conditions is still a matter of debate (Moody et al., 2017). There is also very little empirical and theoretical information regarding the interactions between the dynamics of elemental stoichiometry and that of nitrogen fixation (Pahlow et al., 2013), the latter affecting not only the focal organism's stoichiometry but also that of the rest of its community. Although current laboratory work aims to fill the knowledge gap regarding species-specific responses to different environmental conditions (e.g., Edwards et al., 2015; Mouginot et al., 2015), additional multidisciplinary efforts combining field, laboratory, and models are needed in order to unravel the dynamics of microbial stoichiometry.

Functional Trade-Offs

The efficiency of resource acquisition and utilization determines species competitive ability, and therefore contributes to its fitness. Several models have been proposed to mathematically encode nutrient uptake and its investment in population growth. One of the first attempts is the so-called Michaelis-Menten equation, in which cell growth is a saturating function of the concentration of external resources (Monod, 1949). The MM model assumes that resource uptake leads to growth *instantaneously*. Therefore, in this model there is no difference between both processes (uptake and growth) and they are perfectly coupled. However, even though this assumption provides a moderately accurate picture for constant or low-frequency fluctuating environments (Grover, 1990), the MM model may fail under high-frequency fluctuating conditions because it does not consider cell storage effects. A more detailed description is provided by the so-called Droop model of internal store (Grover, 1991), in which the level of nutrients stored in the cell (*i.e.*, the cell quota) is described explicitly.

Internal store models consider that resource uptake and cell growth are two sequential processes that are decoupled. Resource uptake rate ($\text{mmol cell}^{-1} \text{ day}^{-1}$) is represented by a saturating function $U(R)$ of the concentration of external resources R (mmol m^{-3}), such as the canonical MM model (see Eq. (1)). Once absorbed, resources accumulate in the cell and determine the specific growth rate (d^{-1}) as a saturating function $\mu(Q)$ of the internal quota of resources Q (mmol cell^{-1}). In a seminal work (Droop, 1973), Droop proposed the following saturating dependence between growth rate and cell quota that has been widely used since:

$$\mu(Q) = \mu_{\infty} \left(1 - \frac{Q_{\min}}{Q} \right) \quad (30)$$

where Q is the concentration of intracellular resources, μ_{∞} the specific growth rate at infinite quota, and $Q_{\min}$ the minimum quota required for growth (Fig. 3(b)). The parameters in Eq. (1) and Eq. (32) define a spectrum of resource acquisition and utilization strategies, and thus impact the species fitness. Therefore, they can be understood as functional traits (Violle et al., 2007). Alternative forms of the Droop model can take into account the maximum storage capacity of the cell ($Q_{\max}$) by replacing the constant μ_{∞} by $\mu_{\infty} = \mu_{\max} / (1 - Q_{\min}/Q_{\max})$, where $\mu_{\max}$ is the maximum specific growth rate at full storage of resources (Grover, 1997).

If parameters A , $U_{\max}$, $Q_{\min}$, $Q_{\max}$ and $\mu_{\max}$ in Eqs. (1) and (32) were independent from each other, it would be possible to evolve a super-species with the strongest competitive abilities regardless of the environmental conditions, often termed "Darwinian demon". However, due to physiological constraints, functional traits very often correlate with each other in a way that one trait cannot increase indefinitely without the decrease of another (Fig. 3(c)). These correlations lead to *trade-offs*, *i.e.*, situations in which improving in one task weakens the performance in another task, and thus to the evolution of ecological strategies that are only selected for in a narrow range of environmental conditions.

One of such trade-offs, experimentally measured in bacteria and phytoplankton (Button et al., 2004; Elbing et al., 2004; Healey and Hendzel, 1980), appears to exist between specific affinity α_p and specific maximum uptake rate $\rho_{\max}$ (Litchman et al., 2015b; Vallina et al., 2017) such that $\rho_{\max} \times \alpha_p = \text{constant}$, although the thermodynamic basis of this trade-off are yet unclear (Wirtz, 2002). This "affinity *versus* handling-rate" trade-off defines a spectrum of resource uptake strategies from gleaners to opportunists, each of

Fig. 3 (a) Uptake rate as a function of the external nutrient concentration as defined in Eq. (2) – the gray dashed line represents ρ_{max} ; (b) Growth rate as a function of cell quota – the gray dashed line represents μ_{max} and the dotted line represents Q_{min} ; (c) Three possible shapes for two-trait trade-offs depending on how changes in one of the traits impact the other.

Fig. 4 A “gleaner vs. opportunist” trade-off of the type $\rho_{max} \times \alpha_p = \text{constant}$ leads to: (Left panel) a plane in a 3D space that relates three cell traits, specifically: affinity rate per transporter ($\text{m}^3 \text{ site}^{-1} \text{ day}^{-1}$), handling rate per transporter ($\text{mmol site}^{-1} \text{ day}^{-1}$), and number of transporters per cell (sites cell^{-1}), none of which can be maximized without minimizing another. (Right panel) an array of uptake strategies that gradually go from gleaner ecotypes (blue color) to opportunist ecotypes (red color) as measured from their biomass-specific uptake rate $\rho(R)$ (day^{-1}). Under fluctuating conditions of resource concentration, each of these strategies will dominate the community at their optimal nutrient concentration that is given by $N_{opt} = \rho_{max} / \alpha_p = K_R$ (half-saturation constant – mmol m^{-3}), where α_p is the specific affinity ($\text{m}^3 \text{ mmol}^{-1} \text{ day}^{-1}$) and ρ_{max} is the specific maximum uptake rate (day^{-1}) of each microbial ecotype. Under steady-state conditions, the uptake strategy with lowest R_{star} (see Eq. (34)) will tend to outcompete all other strategies asymptotically in time.

them adapted to different resource concentrations (see Fig. 4). High affinities (and hence low ρ_{max}) constitute gleaner strategies that are favored at low concentrations of resources, while low affinities (and hence high ρ_{max}) constitute opportunistic strategies that are better competitors at high concentrations of resources (see Fig. 4) (Fiksen et al., 2013; Grover, 1997). The root of this trade-off is the way uptake sites are packed in the finite cell surface (Aksnes and Egge, 1991) (see Eq. (3)). Assuming a fixed cell size: (1) for a constant handling rate per transporter (h), decreasing the number of transporters (n) while increasing their affinity (a) will lead to a gleaner strategy (and *vice-versa*); (2) for a constant affinity per transporter, decreasing the number of transporters while increasing their handling rate will lead to an opportunist strategy (and *vice-versa*); and (3) for a constant number of transporters per cell, increasing their handling rate while decreasing their affinity rate will lead to an opportunist strategy (and *vice-versa*); this last case provides the fastest transition from one strategy to the other (e.g., from blue to red in Fig. 4). Finally, decreasing the number of transporters while increasing both their affinity and handling rates will lead to basically no change in the uptake strategy (see Fig. 4). The affinity of a transporter increases with its active area, and the handling rate of a transporter increases with the speed at which the carrier protein change its shape when it moves molecules across the membrane (see Fig. 1) although the exact mechanism is not well understood.

A variable cell size with a constant per-surface density of transporters (i.e., the proportion of the cell’s surface covered by uptake sites) can also affect biomass-specific uptake rates. For a constant per-transporter affinity (a) and handling rate (h), both the specific affinity (α_p) and maximum uptake rate (ρ_{max}) should in theory decrease with cell size due to a concomitant decrease in the surface-to-volume ratio (Aksnes and Egge, 1991). There is strong experimental support for these allometric relationships for marine

phytoplankton (Edwards et al., 2012) and the ecological implication is that the ability to compete for limiting nutrients should tend to decline with increasing cell volume in microbes (Chisholm, 1992). However other physiological limitations and trade-offs can appear with cell size, complicating this picture (Lindemann et al., 2016). For example, small cells (<10 μm) have several physiological constraints (e.g., nonscalable components) that lead to low ρ_{max} (Marañón, 2015; Marañón et al., 2013). These limitations are less acute for larger cells because there is more internal space for catalytic and biosynthetic units, although other physiological constraints such as intracellular distances arise for much larger cells (Marañón, 2015). Large phytoplankton cells, such as diatoms, also have vacuoles that provide a high storage capacity for nutrients. These processes may help attenuate the negative effect of cell size on their biomass-specific effective growth rate and explain why relatively large cells (10–40 μm) usually have a dominant contribution (>50%) to total biomass under blooming conditions of opportunist phytoplankton (Marañón, 2015).

Since cell metabolism and functional traits are strongly linked to the microorganisms' size (Kempes et al., 2012; Marañón, 2015), they may also correlate with other traits, such as susceptibility to viral attacks or predation risk, that are influenced by cell size (Litchman and Klausmeier, 2008). Furthermore, due to the differences in species competitive ability at different external nutrient concentrations of the affinity – handling-rate (or gleaner – opportunist) trade-off defined earlier, if resources are provided in pulses rather than with a constant supply, the optimal uptake strategy changes as resources are depleted, leading to the formation of temporal niches that may favor the coexistence of competitors (Cermenio et al., 2011; Vallina et al., 2017). Functional traits and trade-offs are thus not only important at the level of the individual, determined by physiological constraints and controlling individual performance; they also have fundamental implications in species competitive ability and ultimately impact population dynamics and community composition (Litchman et al., 2015b; Litchman and Klausmeier, 2008; Tilman et al., 1982). Additional processes, such as spatial heterogeneities in nutrient availability or in population density also foster species coexistence and contribute to explaining global patterns of species distributions (Martínez-García and Tarnita, 2017; Tarnita et al., 2015; Vallina et al., 2014b).

In addition to the trade-off in resource acquisition discussed above, other trade-offs linking nutrient acquisition and utilization have been quantified in microbes. For instance, three major strategies have been defined for phosphorus acquisition in phytoplankton (Litchman and Klausmeier, 2008): (i) rate-adapted species, represented by high uptake rate (ρ_{max}) and high growth rate (μ_{max}); (ii) storage specialist, represented by high ρ_{max} but low μ_{max} ; and (iii) affinity-adapted species, represented by low ρ_{max} and high affinity α_p (Crowley, 1975). Related trade-offs have been also found between resource use efficiency and growth rate or between the use of different resources (nitrogen *versus* phosphorous) in phytoplankton (Grover, 1997). Moreover, even though we have placed the focus here in competition for a shared resource as a fundamental driver of community composition, trade-offs have been also studied, both experimentally and theoretically, between different resource utilization abilities (Posfai et al., 2017). Finally, trade-offs also emerge in many other aspects of microbial lives, such as biofilm production (Nadell and Bassler, 2011), sporulation (Martínez-García and Tarnita, 2016; Wolf et al., 2015) or chemotaxis (Yi and Dean, 2016). They also control various ecological processes that underlie the composition, dynamics and stability of microbial communities, such as dispersal to new environments, dormancy or foraging (see also Section “Social Behavior in Microbes”).

Food Web Dynamics

Models of microbial food webs focus on simulating the flux of mass among species at different trophic levels (Mostajir et al., 2015). The structure of such interactions is usually represented with a network in which each node represents a species and links represent the existence of interactions between them. Food webs are a subclass of ecological networks (Montoya et al., 2006; Xiao et al., 2017) in which species are connected by prey–predator interactions (Allesina et al., 2008; Allesina and Pascual, 2008; Thompson et al., 2012). Planktonic communities of unicellular organisms, dominated by protists (unicellular algae and protozoa), bacteria, and viruses (Smetacek, 2002) constitute one of the best studied examples of microbial food webs. They were traditionally seen as linear food chains (Steele, 1974) until the discovery of feedbacks between the species in higher and lower trophic levels, termed the *microbial loop*, emphasized the complexity of their structure (Azam, 1998; Pomeroy et al., 2007) (Fig. 5). Another example of microbial food webs are soil microbial communities, whose dynamics may shed light on the flows of energy that govern below-ground decomposition processes and nutrient cycling (Scheu, 2002). The existence of prey–predator interactions leads to negative correlations among predator and prey populations (i.e., an increase in the abundance of predators leads to a decrease of their prey) (Wangersky, 1978). Population dynamics in food web models is remarkably rich and complex, ranging from equilibrium to oscillations and chaos (Fussmann and Heber, 2002; Huisman and Weissing, 1999; Murray, 2002b).

The general equation describing the dynamics of a food web, assuming linear Lotka-Volterra (LV) interactions, is:

$$\dot{x}_j = x_j \left(\sum_i \alpha_{ji} x_i - m_j \right) = x_j g_j(\mathbf{x}) \quad (31)$$

where $\dot{x}_j$ ($\text{mmol m}^{-3} \text{d}^{-1}$) represents the rate of change in the concentration of focal species j (mmol m^{-3}); α_{ji} ($\text{m}^3 \text{mmol}^{-1} \text{d}^{-1}$) is the strength of the interaction of species i upon species j (which is positive when i is a prey of j and negative when i is a predator of j); and m_j (d^{-1}) gives the background mortality rate of species j (see Box 2). LV equations assume that the predator–prey (i.e., resource–consumer) interactions do not saturate at high prey concentration because the biomass-specific handling rate of the predators is much higher than their biomass-specific affinity ($\rho_{ji}^{\text{max}} \gg \alpha_{ji}$). Hence, the interaction is mainly governed by the affinity

Fig. 5 Simplified marine food web incorporating both a food chain between different types of plankton (black arrows) and the microbial loop (blue arrows), mediated by the decomposed organic matter. Box 2 Lotka-Volterra food webs – Steady states

Resource-ratio (R^* rule)

$$\begin{aligned}\frac{dx_j}{dt} &= \text{NetGrowth} - \text{NaturalMort} \\ \frac{dx_j}{dt} \Big|_{x^*} &= (\alpha_j R - m_j) x_j = 0 \\ (\alpha_j R - m_j) x_j &= 0 \\ R^* &= \frac{m_j}{\alpha_j} \left(\frac{\text{Mortality rate of consumer } x_j \text{ upon resource } R}{\text{Affinity rate of consumer } x_j \text{ upon resource } R} \right)\end{aligned}\quad (32)$$

Food Chain ($h = j - 1 < j < k = j + 1$)

$$\begin{aligned}\frac{dx_j}{dt} &= \text{NetGrowth} - \text{GrazingMort} - \text{NaturalMort} \\ \frac{dx_j}{dt} \Big|_{x^*} &= (\alpha_j x_h - \alpha_k x_k - m_j) x_j = 0 \\ (\alpha_j x_h - \alpha_k x_k - m_j) x_j &= 0 \\ x_h^* &= \frac{m_j + (\alpha_k x_k^*)}{\alpha_j} = \left(\frac{\text{Mortality rate of predator } x_j \text{ upon prey } x_h}{\text{Affinity rate of predator } x_j \text{ upon prey } x_h} \right)\end{aligned}\quad (33)$$

Food Web ($h = \text{prey} < j < k = \text{predator}$)

$$\begin{aligned}\frac{dx_j}{dt} &= \text{NetGrowth} - \text{GrazingMort} - \text{SelfMort} - \text{NaturalMort} \\ \frac{dx_j}{dt} \Big|_{x^*} &= \left(\sum_h \alpha_{jh} x_h - \sum_k \alpha_{jk} x_k - \alpha_{jj} x_j - m_j \right) x_j = 0 \\ \left(\sum_i \alpha_{ji} x_i - m_j \right) x_j &= 0 \\ \sum_i \alpha_{ji} x_i^* &= m_j\end{aligned}\quad (34)$$

Matrix notation

$$\begin{aligned}\dot{x}_j &= x_j^j \left(\sum_i \alpha_{ji} x_i - m_j \right) = 0 \\ \dot{\mathbf{x}} &= \text{diag}(\mathbf{x})(\mathbf{A}\mathbf{x} - \mathbf{m}) = \mathbf{0} \\ \mathbf{x}^* &= \text{inv}(\mathbf{A}) \mathbf{m} \approx \left(\frac{\text{Mortality rate of all predators } j > i \text{ upon prey } x_i}{\text{Affinity rate of all predators } j > i \text{ upon prey } x_i} \right)\end{aligned}\quad (35)$$

(see Eq. (2) after assuming that $\alpha_p/\rho_{max} \approx 0$). Furthermore, even if we relax this constrain, the assumption of a linear functional response between predator may still be valid when prey concentration is relatively low. For example, for prey i concentration values lower than the 25% of the predators j half-saturation constant $K_{ji} = \rho_{ji}^{max} / \alpha_{ji}$ (mmol m^{-3}) the linear approximation and the non-linear saturating curve are quite similar (see Fig. 2). This implies that the LV model assumes that the food web interactions are essentially limited by the encounter rate between predator and prey, either because of the fast handling rate of predators and/or because of the low concentration of prey.

The α_{ji} values are the elements of the Interaction matrix ($\mathbf{A}$) of the LV food web. Element $\alpha_{ji} = \partial(x'_j/x_j)/\partial x_i$ ($\text{m}^3 \text{mmol}^{-1} \text{d}^{-1}$) provides the linear effect that a small change in the concentration of species i has on the biomass-specific rate of change (x'_j/x_j) of species j (Novak et al., 2016). From a mathematical point of view, the Interaction matrix is related to the Jacobian matrix ($\mathbf{J}$) of the LV model linearised around the steady-state equilibrium $\mathbf{x}^*$, because $\mathbf{J} = \text{diag}(\mathbf{x}^*) \mathbf{A}$ (see Box 3). The elements $\mu_{ji} = \partial \dot{x}_j / \partial x_i$ (d^{-1}) of

Box 3 Lotka-Volterra food webs – Stability analysis

The general form a multi-species food web ecosystem model is:

$$\frac{dx_j}{dt} \equiv \dot{x}_j = g_j(x_1, x_2, \dots, x_N) x_j = g_j(\mathbf{x}) x_j = f_j(\mathbf{x}) \quad (36)$$

where x_j (mol m^{-3}) refers to a given state-variable j in the ecosystem that can change with time ($x_j \equiv x_j(t)$), such as the concentration of one species when it refers to a biotic variable or the concentration of abiotic nutrients if they are explicitly resolved in the model. The integer value N gives the total number of variables in the ecosystem; and $g_j(\mathbf{x})$ gives the specific rate of change (d^{-1}) of x_j as a non-linear function g_j of the concentration of the relevant interacting variables specified as a vector $\mathbf{x} = x_1, x_2, \dots, x_N$. When $g_j(\mathbf{x}) > 0$ the population x_j grows, and when $g_j(\mathbf{x}) < 0$ the population x_j decreases. Therefore $\dot{\mathbf{x}}_j = f_j(\mathbf{x})$ gives the absolute rate of change ($\text{mol m}^{-3} \text{d}^{-1}$) of variable x_j at any time as a function of its non-linear interactions with the other variables in the food web. Solving (integrating in time) this system of differential equations gives the time series of each variable x_j . The species concentration in the steady-state ($\mathbf{x}^*$) are the *fixed points* of Eq. (36), which are obtained by setting all the rates of change $\dot{x}_j$ for all j equal to zero:

$$\dot{x}_j = f_j(\mathbf{x}^*) = 0 \quad (37)$$

A fixed point is defined as any vector $\mathbf{x}^*$ with coordinates $(x^*_1, x^*_2, \dots, x^*_N)$ in the phase space in which the concentration of the variables do not change with time (*i.e.*, the time series are flat). It is possible that a system has more than one feasible (*i.e.*, with positive concentrations) fixed point and therefore multiple steady-states. A steady state can be locally stable, neutrally stable, or unstable; depending on the dynamics of the system in the vicinity of the fixed point (see Fig. 6). Thus in order to study that dynamics, we add an infinitesimal perturbation to each steady-state concentration:

$$\mathbf{x}(t) = \mathbf{x}^* + \Delta \mathbf{x}(t) \quad (38)$$

where $\Delta \mathbf{x}(t=0) = \varepsilon \mathbf{x}^*$ with $\varepsilon \ll 1$, and calculate the change of the perturbation $\Delta \mathbf{x}(t) = \mathbf{x}(t) - \mathbf{x}^*$ over time. When $\Delta \mathbf{x}(t) > 0$ the perturbed community departs from its fixed point (which is thus unstable), and when $\Delta \mathbf{x}(t) < 0$ the perturbed community returns to its fixed point (which is thus stable). To study the change with time of this perturbed community $\Delta \mathbf{x}(t)$ by means of Eq. (36) we need to *linearise* the original non-linear system around the fixed point. This will give a linear approximation of the original non-linear system only valid for small departures from the steady-state. For larger perturbations, the behavior of the linear system can be significantly different to that of the original non-linear one, and the approximation may no longer be valid. To linearise Eq. (36), we obtain its Taylor expansion around the fixed point and neglect terms of second order (*i.e.*, $O(\varepsilon^2)$) and higher (May, 1974; Novak et al., 2016):

$$\Delta \dot{x}_j \approx \sum_{i=1}^N \frac{\partial f_j(\mathbf{x}^*)}{\partial x_i} \Delta x_i = \sum_{i=1}^N (\alpha_{ji} x_j^*) \Delta x_i = \sum_{i=1}^N (\mu_{ji} \Delta x_i) \quad (39)$$

$$\alpha_{ji} = \left. \frac{\partial (\dot{x}_j/x_j)}{\partial x_i} \right|_{\mathbf{x}^*} \quad \mu_{ji} = \left. \frac{\partial \dot{x}_j}{\partial x_i} \right|_{\mathbf{x}^*} \quad (40)$$

where α_{ji} ($\text{m}^3 \text{mol}^{-1} \text{d}^{-1}$) measures the effect of population i on the biomass-specific growth of population j , and $\mu_{ji} = \alpha_{ji} x_j^*$ (d^{-1}) measures the effect of population i on the absolute growth of population j ; both at fixed point $\mathbf{x}^*$ in the linearised system. For example, the value $\mu_{jh} = \alpha_{jh} x_h^*$ defines the (linearised) interaction of prey at lower trophic level h on predator j (growth of j due to ingesting h); the value $\mu_{jk} = -\alpha_{jk} x_k^*$ defines the interaction of predator k on prey at lower trophic level j (mortality of j due to predation by k); and the value $\mu_{jj} = -\alpha_{jj} x_j^*$ defines the interaction of population j on itself (quadratic mortality of j due to intra-specific competition), if any. Note that $\alpha_{jh} = e_j \alpha_{jh}$, where $0 < e_j < 1$ is the assimilation efficiency of population j , which means that predator j has stronger negative effect on the growth rate of prey i than the positive effect that prey i has on the growth rate of predator j . This is because only a fraction of the prey ingested will be assimilated into predators' biomass, which leads to the skewed symmetry of the food web interactions. An equivalent but more compact matrix notation can be used for Eq. (39):

$$\Delta \dot{\mathbf{x}}(t) = \mathbf{J} \Delta \mathbf{x}(t) \quad (41)$$

where $\mathbf{x}$ is the ($N \times 1$) column vector of x_j (mol m^{-3}), $\dot{\mathbf{x}}$ is their absolute rate of change ($\text{mol m}^{-3} \text{d}^{-1}$) and $\mathbf{J} = \partial \dot{\mathbf{x}} / \partial \mathbf{x}$ is the ($N \times N$) Jacobian matrix whose elements μ_{ji} (d^{-1}) are defined in Eq. (40). The off-diagonal elements μ_{ji} of $\mathbf{J}$ measure the inter-specific interactions, while the diagonal elements μ_{jj} measure the intra-specific interactions. Note that linearising a non-linear ecosystem leads to assuming linear Lotka-Volterra (LV) dynamics around its fixed point(s). The analytical solution of this linear ecosystem gives the change with time of the perturbed food web:

$$x_j(t) = x_j^* + \Delta x_j(t) = x_j^* + \sum_{i=1}^N (c_i v_i e^{\lambda_i t}) \quad (42)$$

(Continued)

Box 3 (Continued)

where c_i are constants, and λ_i are the *eigenvalues* corresponding to the *eigenvectors* $\mathbf{v}_i$ of the Jacobian matrix such as $\mathbf{J} \mathbf{v}_i = \lambda_i \mathbf{v}_i$. This simply means that a linear transformation $\mathbf{J}$ applied to $\mathbf{v}_i$ (eigenvector i) may change its length by a factor λ_i (eigenvalue i). Thus the eigenvectors of $\mathbf{J}$ can be stretched (unstable) or contracted (stable) by their eigenvalues, but they do not change direction because they are linearly independent among them. The eigenvalues may be complex numbers, but the system's resilience is given by their real part. For the system to be *stable* in the vicinity of a given steady-state, (the real part of) all eigenvalues of $\mathbf{J}$ must be negative. This can be easily understood by inspecting Eq. (42): if one (or more) eigenvalues is positive, the perturbation grows exponentially with time and thus that particular fixed point would be unstable. If we define the *dominant* eigenvalue (λ_d) as the largest eigenvalue, a necessary and sufficient condition for stability is that $\lambda_d < 0$. For non-positive eigenvalues if the real part of (at least) the dominant eigenvalue is zero, the steady-state is *neutrally stable* (the perturbation does not move along at least one eigenvector). The eigenvectors with negative eigenvalues form the stable eigenspace (*stable manifold*); the eigenvectors with positive eigenvalues form the unstable eigenspace (*unstable manifold*); the eigenvectors with zero eigenvalues form the neutrally stable eigenspace (*center manifold*). A summary of the several stability regimes of fixed points (e.g., stable or unstable nodes, stable or unstable spirals, unstable saddle points, neutrally stable centers) and their relationship to the two major properties of the Jacobian matrix (its trace and determinant) can be found in Figs. 6 and 7. This asymptotic stability analysis must be performed around all the feasible steady-states of the system (there might be more than one) to obtain the whole picture of the stability properties of the food web ecosystem in its N-dimensional phase-space.

Fig. 6 Examples of the most common trajectory behaviors near fixed point singularities in the phase plane solutions of a two-dimensional continuous-time linear dynamical food web ecosystem (e.g. one predator – one prey) where the red dots are the initial conditions: [Upper left] Unstable node; [Upper middle] Unstable spiral; [Upper right] Saddle point (these are always unstable); [Lower left] Stable node; [Lower middle] Stable spiral; [Lower right] Center (these are neutrally stable).

the Jacobian matrix provide the linear effect of a small change in the concentration of species i on the *absolute* rate of change ($\dot{x}_i$) of species j at equilibrium (Berlow et al., 2004). That is, if a change in the concentration of a given species i does not affect the rate of change of another species j , then they are not linked (either directly or indirectly) in the food web (Novak et al., 2016). When predator i and prey j are connected, then $\alpha_{ji} > e_i \alpha_{ij}$, where $0 < e_i < 1$ is the assimilation efficiency of predator i . Therefore, the Interaction matrix is said to be “skew-symmetric” because the negative effect of predator i on prey j is larger (in absolute magnitude) than the positive effect of prey j on predator i by a constant factor. For the Jacobian matrix this is not necessarily the case because its elements are proportional to the concentration of the species at equilibrium, and inverted biomass pyramids (i.e., top heavy) are possible (Barbier and Loreau, 2019). The Jacobian matrix is important when modelling microbial communities because its eigenvalues inform about the asymptotic stability (Allesina and Tang, 2012; Coyte et al., 2015) of the network to small perturbations of the steady state (i.e., food web resilience – see Box 3). The diagonal elements of the Jacobian (μ_{jj}) represent the strength of

Fig. 7 Summary diagram showing how the trace $\text{tr}(\mathbf{J})$ and determinant $\text{det}(\mathbf{J})$ of the Jacobian matrix ($\mathbf{J}$) define the stability types of fixed points in the phase plane of a two-dimensional continuous-time linear dynamical food chain (e.g., one predator – one prey). Picture credits: © Math24.

the interaction of a species j with itself, and are usually considered to be negative (e.g., intra-specific competition). Negative interactions in these diagonal elements of the Jacobian mimic the existence of a carrying capacity (e.g., through quadratic mortality or self-regulation) for each species, leading to the *logistic equation* (Murray, 2002a). This promotes asymptotic stability of the network at equilibrium by preventing excessive growth of any microbial species (Haydon, 1994). While negative diagonal elements μ_{jj} are stabilizing, the off-diagonal elements μ_{ji} are destabilizing (Neutel et al., 2002). The Jacobian matrix ($\mathbf{J} = \mu_{ji}$) is said to be *negative diagonally dominant* and thus stable (Hofbauer and Sigmund, 1988; Logofet, 1993) if there is a set of positive numbers $\pi_1, \pi_2, \dots, \pi_n$, such that $\pi_j \mu_{jj} + \sum_{i \neq j} \pi_i |\mu_{ji}| < 0$. In other words, if for each species j in the network the intra-specific competition ($\mu_{jj} < 0$) is stronger than the sum of all the inter-specific interactions μ_{ji} affecting species j .

When essential nutrients are not explicitly included in the simulated food web, the nutrient competition among basal species must be implicitly assumed by imposing negative α_{ji} elements in the Interaction matrix. This is probably one of the major criticisms of classical food web models (see Eq. 36), because this simple approach lacks mechanistical foundations. Thus, it is usually advisable to add (at least) one essential abiotic nutrient N to the system by imposing a mass conservation constrain (that is, the total mass N_{tot} must be constant) such that $N = N_{\text{tot}} - \sum_j x_j$ (Grover, 1997). This basically means closing the system in terms of mass circulation and thus that the sum of all the differential equations is zero ($\dot{N} + \sum_j \dot{x}_j = 0$). When this constraint is explicitly included in the simulated food web, introduces a carrying capacity for the *whole* food web (i.e., all nodes) because there is an upper limit to the whole community density given by the total mass N_{tot} in the system. Furthermore, the interaction of consumers that are not connected by predator–prey links but share the same resource(s), may be indirectly channeled through *resource competition* for the same pool of essential nutrients or common prey. That means that there is no need to impose non-zero elements in the Interaction matrix for their interaction. Another interesting feature of any food web (simulated or real) is the presence of indirect interactions among the species comprising the food web: even species that are not linked by direct predator–prey interactions (they don't prey upon each other) can be connected if they share a common predator, leading to *apparent competition* (Holt, 1977; Holt and Bonsall, 2017).

The temporal dynamics of food webs depends, therefore, on both bottom-up and top-down controls (de Ruiter et al., 1995). Resource supply acts as bottom-up control, while predator (or virus) induced mortality acts as top-down control. This mesh of interactions is usually composed by many weak and few strong linkages between species (Neutel et al., 2002). Top-down controls can be either stabilizing or destabilizing of food web dynamics depending on the functional form of the predatory response (Abrams and Allison, 1982; Haydon, 1994). While the LV equations assume linear functional relationships, more mechanistically driven models of microbial food webs use non-linear functional forms (Ward et al., 2012). In addition, food web models can include killing-the-winner (KTW) mortality of microbial communities, either by viral infection (Thingstad, 2000; Winter et al., 2010) or by preferential grazing (Vallina et al., 2014b). KTW is known to stabilize food web dynamics because it is an equalizing mechanism that “down-regulate the winners and up-regulate the losers” through density-dependent mortality

(i.e., predator-mediated coexistence). KTW has a similar effect as density-dependent (e.g., quadratic) self-mortality because it also makes the diagonal elements of the Jacobian to be more negative (Haydon, 1994). Since trophic relationships add potential interactions among species, both directly and indirectly, microbial food webs bring together population-, trophic-, and ecosystem-level processes. The existence of these connections across and within different levels opens the possibility for trophic cascades (Duffy et al., 2007) and positions species interactions as biological filters that can propagate environmentally-driven fluctuations in species densities throughout the community (Ives et al., 2003; Ives et al., 2000). Although food webs have thus been suggested to amplify environmental fluctuations (Barbier and Loreau, 2019; Ives et al., 2003), this theoretical prediction assumes linear interactions between species for mathematical simplicity and analytical tractability. More realistic interactions are known to be highly non-linear (e.g., density-dependent interactions). Thus, due to non-linearities, food webs could be biological filters that actually dampen environmental perturbations throughout the community.

Loop length and loop weight analyses (LLA, LWA) are mathematical tools for exploring the structure and organization of trophic food webs by studying how the strength of feeding interactions affects the stability of the system. Loop length is defined as the number of different species visited through a closed pathway of interactions (i.e., ending back to the starting species) without visiting other species more than once. Loop weight is defined as the geometric mean of the absolute values of the interaction strengths in a loop (Neutel et al., 2002). The skewed combination of many weak and few strong links of predator-prey interactions within long network loops has been suggested to increase the stability of food webs (Neutel et al., 2002). However, this prediction is based on rigid non-selective predator-prey interactions, which are known to lead to ecosystem instability if they are too strong (Neutel et al., 2007). The relative contribution of weak and strong links in microbial communities may be affected by more flexible KTW interactions. In addition to loop length and loop weight, other topological properties of networks related to stability are connectivity, interaction strength, centrality, modularity and nestedness (Berlow et al., 2004; Landi et al., 2018). Connectivity measures the density of links in the network; interaction strength measures how strong these links are; centrality measures how important a node is in the network (e.g., keystone species), either because it is highly connected (to many other nodes), does so strongly (channels large flows of mass energy), or because it governs many indirect interactions and/or can trigger many secondary extinctions if the node is removed (Dunne et al., 2002); modularity implies that the network is composed of distinct and densely connected subsystems (Grilli et al., 2016); nestedness means that the diet of the most specialized species is a subset of the diet of the next more generalized species, and its diet a subset of the next more generalized, and so on (Montoya et al., 2006). These properties define the patterns of ecological networks and are used to evaluate their stability and robustness (Grilli et al., 2016; Montoya et al., 2006).

Despite the extensive research and the many models developed during the last four decades, the exact mechanisms that stabilize food webs are yet not fully understood. Early work focused on measures of stability at equilibrium (see Box 3) and predicted that more complex food webs should lead to more unstable ecosystems (Harrison, 1979; May, 1974; Pimm, 1984). However, these predictions are challenged by field observations in both terrestrial and aquatic systems, and thus newer theories have moved the focus to aggregated community-level propertiral equation describing the dynamics of a foes under non-equilibrium conditions (Loreau, 2010a). Yet, the analysis of microbial food web models in the steady-state is a powerful tool to predict the outcome of competition in microbial communities (i.e., species persistence) subject to lab-controlled conditions such as chemostat bioreactors (Grover, 1997; Tilman, 1982). Assuming LV interactions (Lotka, 1920; Volterra, 1928), we can predict the steady-state abundance of the different populations that form the food web. For the simplest case of a trophic interaction composed of one abiotic resource shared by several consumers, the “R-star” rule applies. The concentration of the resource at equilibrium (R^*) in a mono-culture of the consumer is given by the ratio between the mortality rate (m_j) and the uptake affinity (α_j) of the consumer j (see Eq. (35) in Box 2). The consumer that is able to subsist at the lowest resource concentration after reaching equilibrium (i.e., lowest R^*) will eventually outcompete all other consumers (Tilman, 1982). However, this theoretical prediction only holds in the absence of stabilizing mechanisms (e.g., self-regulation), which can lead to some degree of species coexistence at steady-state (see above). The same rule applies to food webs, considering that the consumers j at lower trophic levels are the resources of consumers k at higher trophic levels. In the simplest scenario of linear food chains there is only one species per trophic level, and the concentration at equilibrium of the species at trophic level $(j - 1)$ is given by the ratio between the mortality rate and the grazing affinity of its consumer at trophic level j (see Eq. (36) in Box 2). Note that the equilibrium of each species does not depend on their own physiological traits but on those of their predators. Food chains based on linear predator-prey interactions have been very influential in the development of ecological theory and understanding their dynamics serves as the cornerstone for studying more complex food webs and functional responses (see Barbier and Loreau, 2019 for a review). For the most complex case of a multi-species and multi-trophic level food web, considering that species in a given trophic level j may serve as resource of the consumers at several trophic levels above it ($k > j$), the steady-state of x_j will depend on the ratio between a combination of the mortality rates and grazing affinities of those higher-trophic level consumers feeding on him (see Eq. (38) in Box 2).

Assuming a more realistic Michaelis-Menten (MM) formulation for resource-consumer interactions (see Section “Uptake Machinery”), because it accounts for consumer saturation at high resource concentration, leads to a slightly different expression for the “R-star” expression:

$$R^* = \frac{m_i}{\alpha_i - m_i / \rho_i^{\max}} \quad (43)$$

Most food web models are based on variants of the MM formulation for resource-consumer interactions (Gilljam et al., 2015), where the R^* rule still applies at equilibrium. However, the R^* rule cannot predict the outcome of competition under

non-equilibrium conditions when there is a trade-off between resource uptake affinity (α_i) and maximum uptake rate (ρ_i^{max}) (see Section “Functional Trade-Offs”). The best known example occurs when under pulsed nutrient supply, high-nutrient-adapted ecotypes (HNA – which are opportunists with high ρ_i^{max}) can outcompete low-nutrient-adapted ecotypes (LNA – which are gleaners with high α_i). This occurs even if LNA ecotypes have lower R^* than HNA ecotypes and would otherwise dominate the community at steady-state equilibrium (Cermenio et al., 2011). The MM formulation can simulate this trade-off, which happens when the uptake curves of two consumers intersect at some resource concentration (see Fig. 4). However, the LV formulation does not account for this trade-off because LV equations assume that $\rho_{ji}^{max} \gg \alpha_{ji}$, and thus that the resource-consumer interactions are governed by just α_{ji} (i.e., without saturation at high resource concentration). Therefore, in non-equilibrium environments it is advisable to use the MM equations to simulate resource–consumer interactions in microbial food webs, and restrict the use of the LV equations to the linear stability analysis of steady-states (see Box 3). Thus, the R^* rule derived for equilibrium conditions (either using LV or MM equations) is useful but does not always apply to most natural ecosystems, in which microbial communities are subject to non-equilibrium environmental conditions and physiological trade-offs are the norm (Barton et al., 2010; Litchman and Klausmeier, 2008). Furthermore, under non-equilibrium environmental conditions, classic equilibrium theory to compute ecosystem resilience (see Box 3) does not apply, and other metrics such as the standard deviation of the population time-series are more informative (Vallina and Le Quéré, 2011). Recognizing that most microbial ecosystems are subject to non-equilibrium environmental conditions has also opened the door to a reconciliation between earlier theoretical models, whose predictions assumed that populations are in the steady-state equilibrium, and more recent numerical models that enable predictions for non-equilibrium situations (Barton et al., 2010; Vallina et al., 2017).

Ecological Selection and Community Assembly

The concept of “assembly rules” was proposed almost 40 years ago and refers to the fundamental mechanisms that govern how species associate to form a community. This concept defines the theoretical conditions for species persistence depending on their trait values (Diamond, 1975; Grover, 1997) and it is thus related to what is known as “ecological selection” (see below). One of the most intriguing aspects regarding microbial community assembling is how to explain the maintenance of species and trait diversity – what are the mechanisms that allow so many different and competing species to coexist within the same ecological niche? The *competitive exclusion principle* states that two species that occupy the same ecological niche cannot coexist indefinitely (Hardin, 1960). The rate of competitive exclusion depends on the degree of niche overlap and the particular trait values of the competing species (Vallina et al., 2017). Large niche overlap and larger differences in trait values lead to faster exclusion rates than small niche overlap and smaller differences in trait values. When such niches are defined by shared resources (maximum overlap), the competitive exclusion principle translates into the *theory of limiting nutrients*, which states that there cannot be more coexisting species than the number of *essential resources* (Tilman, 1982) (see Section “Food Web Dynamics” – “R-star” rule).

Ecological selection is directly related to *invasion fitness* (see Box 4) and competitive exclusion (Gause, 1934), as it works upon a multi-species community until only the set of best adapted species (a fraction of the original pool) survive locally. Ecological selection leads to the “survival of the fittest” through competitive exclusion on ecological time-scales, i.e., before longer-term evolutionary dynamics can take place (Falkowski and Oliver, 2007). The best adapted species to a particular environment or ecological niche will dominate the local community. Thus, the system may be dynamically unstable, even in the absence of environmental changes, because species extinctions may occur locally until a stable community is reached for the current environmental conditions. When the environmental conditions change, a new and different microbial community may self-assemble de-novo through ecological selection if there is exchange of species with other communities or if there is a local pool of rare (non-dominant) ecotypes available (Follows et al., 2007; Pedros-Alio, 2012). Ecological selection can thus be defined in the context of *niche space*, which can be categorized in two classes: fundamental niche and realized niche. The *fundamental niche* of a given species defines the environmental conditions that are suitable for growth in the absence of interactions with other species, while the *realized niche* defines the environmental conditions where a given species is actually observed when it is interacting with other species (Hutchinson, 1957b). Therefore, the realized niche may be narrower than the fundamental niche, due to the exploitative competition among the interacting species.

Community assembly in soil ecosystems can be affected by agricultural practices and thus there is a well developed theoretical framework to simulate the observed patterns at equilibrium (de Ruiter et al., 1993; de Ruiter et al., 1995; Kaunzinger and Morin, 1998; Neutel et al., 2002, 2007). Metabolic modelling under a reverse-ecology framework has also been used to successfully elucidate the assembly rules of the human microbiome at the community-level, suggesting that microbiome assembly is dominated by environmental filtering (Levy and Borenstein, 2013, 2014). Aquatic environments are among the best studied examples of how ecological selection may operate for the community assembly of microbial communities (see Fig. 8) (Follows and Dutkiewicz, 2011; Litchman and Klausmeier, 2008). Microbial cells such as bacterioplankton and phytoplankton, are suspended in a generally well-mixed medium and compete for the same essential resources from a common and spatially fairly homogeneous pool, which implies that all individuals are potentially interacting with each other (Sommer, 2002). However, field observations contradict theoretical predictions and show that there is a much larger number of coexisting species than of non-substitutable resources (e.g., elemental nutrients) in the ocean, which has led to what is known as the “Paradox of the Plankton” (Hutchinson, 1961). Theoretical studies have suggested several hypotheses in order to account for this discrepancy between theoretical predictions and field observations. There are several conceptual frameworks that have been explicitly invoked to explain the assembly of microbial

Box 4 Ecological fitness.

$$\begin{aligned}
\frac{\partial x_j}{\partial t} &= \text{NetGrowth} - \text{NaturalMort} \\
&= \mu_j^{\max} (\gamma_j^N \gamma_j^T \gamma_j^I) x_j - m_j x_j \\
&= \mu_j x_j - m_j x_j \\
&= (\mu_j - m_j) x_j \\
&= \lambda_j x_j
\end{aligned} \tag{44}$$

where:

$$\gamma_j^N = \frac{N}{(\mu_j^{\max} / \alpha_j) + N} \leq 1 \tag{45}$$

$$\gamma_j^T = \frac{\exp(-(T_j^{\text{opt}} - T)^2)}{(2\sigma_T^2)} \leq 1 \tag{46}$$

$$\gamma_j^I = \frac{I}{I_j^{\text{opt}}} \exp\left(1 - \frac{I}{I_j^{\text{opt}}}\right) \leq 1 \tag{47}$$

The parameter $\lambda_j \leq \mu_j^{\max}$ gives the specific rate of change of microbial ecotype j in units of inverse time (d^{-1}), and is a measure of their ecological (*i.e.*, invasion) fitness that depends on the environmental conditions affecting their maximum growth rate $\mu_j^{\max}$. The parameters γ_j^N , γ_j^T and γ_j^I determine the nutrient limitation, temperature limitation and irradiance limitation for microbial ecotype j , respectively. This model assumes that the effect of these three environmental factors on fitness is multiplicative, which implies that they are considered to be independent factors co-limiting growth (Fasham et al., 1990; Follows et al., 2007). The physiological traits of the different ecotypes will determine their optimal values of nutrient concentration (N_j^{opt}), optimal temperature (T_j^{opt}), and optimal irradiance (I_j^{opt}). These three coordinates (N_j^{opt} , T_j^{opt} , I_j^{opt}) define the environmental niches where each ecotype is the best competitor (see Fig. 9), and thus its location in the niche space (see Fig. 9, lower panel). Note that $N_j^{\text{opt}} = K_j^{\text{sat}} = (\mu_j^{\max} / \alpha_j)$ when a gleaner-opportunist trade-off is assumed (see Section “Functional Trade-Offs”). Therefore, for a given set of environmental conditions, ecological selection will lead to a community dominated by the fittest ecotypes. Changes in the environmental conditions modify the fitness of each ecotype and also the composition of the community (*i.e.*, beta diversity; see Section “Biodiversity and Ecosystem Functioning”).

Fig. 8 The combination of different genotypes, different environmental conditions, and global ocean dispersal leads the “ecological selection” of the ecotypes with higher fitness locally, in either space or time. The resulting community assembly and species composition at each location will thus be different depending on the environmental conditions. Therefore, the ecosystem structure and functioning will vary. Furthermore, the environmental conditions will also be affected by the local community and its composition, mostly through nutrient depletion. Therefore there is a feedback between environmental conditions and the ecological selection of locally dominant ecotypes. Picture credits: © Follows, M.J., Dutkiewicz, S., 2011. Modeling diverse communities of marine microbes. *Annual Reviews of Marine Science* 3, 427–451.

communities using mechanistic ecosystem models, such as niche theory for marine algae (Barton et al., 2010; Follows et al., 2007) or the human microbiome (Levy and Borenstein, 2013); neutral theory for generic host-associated microbiomes (Zeng and Rodrigo, 2018); the resource-ratio hypothesis for freshwater algae (Tilman, 1982); the killing-the-winner hypothesis for bacteria (Maslov and Sneppen, 2017; Thingstad, 2000) and phytoplankton (Vallina et al., 2014b); the nutrient-load hypothesis for cyanobacteria and phytoplankton (Brauer et al., 2012); the high-order interactions hypothesis for bacteria (Grilli et al., 2017); and even chaos theory for phytoplankton (Huisman and Weissing, 1999, 2001); among others.

The *niche theory* suggests that species are ecologically unique, which implies that they occupy different environmental niches and fulfill different functional roles (MacArthur, 1968). Therefore, organisms can exploit and partition a set of resources along environmental gradients (e.g., elemental nutrients, prey-size, ambient temperature, solar radiation) by decreasing their niche overlap through specialization (Loreau, 2010a). On the other hand, *neutral theory* suggests that species are ecologically equivalent, which implies that they have a similar competitive strength, slow exclusion rates, and thus can occupy the same environmental niches or fulfill the same functional roles for long periods of time. Under this view, community assembly is governed by random demographic processes such as the rate of immigration from the regional pool (Hubbell, 2001). The *killing-the-winner* hypothesis provides a simple mechanism for stable coexistence due to the presence of a trade-off between competition ability for growth and vulnerability to mortality among the competing species. Higher-abundance species will be proportionally more susceptible to phage or predatory attack, which can eventually result in greater fitness of the lower-abundance species (i.e., the fitness of a phenotype increases as it becomes rarer) (Maslov and Sneppen, 2017; Thingstad, 2000; Vallina et al., 2014b). The resource-ratio hypothesis describes the assembly rules by which species competing for several resources can coexist at intermediate levels of nutrient supply (Tilman, 1982). Finally, high-order interactions theory suggests that the presence of a given species influences the interaction between other species (Billick and Case, 1994; Grilli et al., 2017; Kelsic et al., 2015) and shapes the relationship between ecosystem diversity and stability (Bailey et al., 2016). Recent studies, both theoretical and experimental, have shown that this higher-order interactions are often established through cross-feeding, a class of interspecific interaction in which organisms belonging to one species use metabolites produced and secreted by the other species as energy or nutrient sources (Goldford et al., 2018; Goyal and Maslov, 2018; van Hoek and Merks, 2017) (see Section “Social Behavior in Microbes”).

One fundamental feature of most microbial organisms is their great capacity of passive dispersal by external agents, which affects the population dynamics and community assembly (Cerneno and Falkowski, 2009). Dispersal influences the probability of species to reach distant environments and thus their potential to interact with many other species – hence the common say in microbial ecology “everything is everywhere, but the environment selects” (Baas-Becking, 1934; De Wit and Bouvier, 2006). For instance, aquatic microorganisms are subject to passive advection and turbulent diffusion by water currents; in terrestrial systems, wind plays a similar role. This is generally explicitly included in global ocean models (e.g., Follows et al., 2007). Other means by which microbes are dispersed are within the microbiome or attached to larger organisms. Community assembly theory suggests that the two main processes affecting the spatial and temporal distribution of species trait values are *species competition* and *environmental filtering*. Environmental filtering occurs when a species arrives at a focal site but fails to survive even in the absence of neighbours; competitive exclusion occurs when a species arrives and can persist in the absence of neighbours but not in their presence (Kraft et al., 2015). These processes do not act in isolation, however, and it is the interplay of competition- and filtering-driven fitness that leads to the *ecological selection* of species. Competition leads to ecological differentiation, while filtering reduces the spread of trait values and leads to similar ecological tolerances (Cornwell et al., 2006). Therefore, functional traits determine the species distribution along environmental gradients as well as the species competition for resources within a given environmental niche (Ackerly and Cornwell, 2007). Coexistence between species is thus the result of a balance between stabilizing forces (i.e., niche differences) and equalizing forces (i.e., fitness similarity) (Chesson, 2000a). Stabilizing mechanisms are those that increase the strength of intra-specific competition relative to the strength of inter-specific competition, while equalizing mechanisms are those that reduce the magnitude of the fitness difference (Loreau, 2010a). Stabilizing niche differences facilitate coexistence whereas relative fitness differences drive competitive exclusion.

Thus the niche space can be seen as the hypervolume of environmental conditions under which each microbial ecotype persists (Hutchinson, 1957a). Microbes in natural ecosystems have traits to cope with several environmental gradients, such as nutrient concentration, ambient temperature, solar irradiance, etc (see Fig. 9 upper panels). The patterns of functional trait similarity cannot easily be used to infer the relative contribution of environmental filtering *versus* competitive interaction in shaping the community assembly of microbial communities (Vallina et al., 2017). Competitive exclusion can be avoided by species that are functionally very dissimilar when the difference between the species traits are acting as stabilizing niche differences; e.g., optimal values of temperature and/or solar radiation levels (see Fig. 9 upper panels). However, when differences in species traits directly translate into fitness differences, then competitive exclusion can eliminate the functionally weaker competitors within a given ecological niche (i.e., lower resource exploitation ability) (Chase and Leibold, 2003). The role of species dispersal can further blur the line separating environmental filtering and species competition. Furthermore, microbial communities in aquatic systems live in a very dynamic fluid environment, which implies that their environmental niches are neither stationary nor spatially closed. Therefore, all ecotypes can potential migrate between different niches by passive dispersal and will dominate the community where the environmental conditions match their optimal values (e.g., see Fig. S2 in Follows et al., 2007). A similar effect occurs by wind-mediated dispersal in terrestrial communities (Tarnita et al., 2015).

Dispersal can thus influence the microbial diversity at local and regional scales. The rate of dispersal compared to the rates of competition and/or environmental filtering will determine the actual community assembly and ecosystem structure over larger regions (Clayton et al., 2013). Spatial environmental heterogeneity, coupled to dispersal between different locations, may thus

Fig. 9 Bottom: “Hypercube” setup of a model with 64 phytoplankton species each of them occupying a particular ecological niche given by some of their functional-traits (*i.e.*, optimal levels) for 3 environmental axes: dissolved inorganic nutrients (DIN), water temperature (SST), and photosynthetically active radiation (PAR); Upper: Growth curves and optimum values $\pm$ ecological tolerances of the 64 simulated marine phytoplankton species along those 3 environmental axes (DIN, SST, PAR).

foster species diversity. Temporal heterogeneity may also promote coexistence when alternating environmental conditions within a time period favor different species, which is sometimes called the *storage effect* (Chesson, 2000b; Vallina et al., 2017). Such heterogeneity is characteristic of many real ecosystems that are subject to the effect of seasonal trends in environmental parameters. However, in order to induce a temporal niche partition and thus lead to species coexistence, time-varying environmental conditions need to satisfy two additional requirements: (i) the rate at which populations decline together with the temporal scale of the environment avoids the extinction of non-favored species and (ii) the covariance between environment and competition intensity is opposite for high density and low density species, which allows species to have positive growth rates when they become less abundant and recover larger population sizes. The temporal storage effect was initially proposed to explain coexistence in annual plants, but recent models have extended the concept to sporulating microbes and suggested its potential importance in explaining diversity in certain terrestrial communities of microbes in which dispersal can be neglected (Martínez-García and Tarnita, 2017). The theoretical frameworks and ideas discussed here are the conceptual basis for the mechanisms included in most microbial ecosystem models that are used today.

Ecological Evolution and Community Adaptation

Microbial organisms have the capacity to evolve over hundreds to few thousands of generations in response to environmental variability, even when mutation rates are low, because of their fast replication rates and large population sizes (Elena and Lenski, 2003; Frank and Slatkin, 1990; Hellweger et al., 2014; Huertas et al., 2011; Van den Bergh et al., 2018). Microbial communities are subject to both (i) *ecological selection*, which acts through short-term competitive exclusion between species (see Section “Ecological Selection and Community Assembly”); and (ii) *adaptive evolution*, which provides inheritable change of species-traits and affects the organisms’ fitness after several successive events of ecological selection. Ecological evolution thus refers to the arrangement of organisms along phylogenetic lines (Bews, 1927). The relative influence and interplay of both selection and evolution on the

dynamics of microbial communities is a challenging and fascinating research venue for modelers due to the overlap of temporal scales (Doebeli et al., 2017; Fussmann et al., 2007; Ghoul and Mitri, 2016; MacColl, 2011). Formally, however, there is no difference between ecological and evolutionary dynamics because both are based on the same fundamental birth-death processes (Doebeli et al., 2017). Given the random nature of discrete genetic mutations and their effects on the phenotype, these *eco-evolutionary dynamics* can be studied with stochastic differential equations in continuous time (e.g., Fokker-Planck equation) that approximate the mutation steps as infinitesimally small. Under this view, evolution can be visualized as an uphill walk on “Dynamic Fitness Landscapes” (DFL) that keep changing as a result of the evolution it engenders (Metz, 2011; Mustonen and Lassig, 2009; Richter, 2013; Richter and Engelbrecht, 2014). However DFL are *not* a driver of evolution, they are an emergent property of the underlying stochastic birth-death ecological process (Doebeli et al., 2017). Evolutionary changes in microbial communities thus respond to both local selection pressures as well as population dynamics, because ecological interactions create density-dependent selective pressures that affect gene frequencies (Cordero and Polz, 2014).

Eco-evolutionary dynamics are particularly important for microbial communities because their explicit inclusion of population dynamics into evolutionary models allows evaluation of the potential feedbacks between fitness and organisms (Dieckmann, 1999). Theoretical studies show that species will evolve to maximize their geometric mean fitness in environments that vary stochastically in time. Hence, evolutionary change is expected even if decadal-scale changes are smaller than inter-annual variability (Frank and Slatkin, 1990). An example in which eco-evo feedbacks are relevant is antibiotic-mediated interactions. Microbial evolution in a spatially structured landscape with environmental gradients of antibiotic concentration has even been shown in real time (Baym et al., 2016). The evolution of cancer cells may also impose limits to the predictability of precision cancer medicine (Lipinski et al., 2016). Several studies have addressed the effect of eco-evolutionary feedbacks under different microbial scenarios (Bonachela et al., 2017; Kotil and Vetsigian, 2018; Martin et al., 2016; Tarnita, 2018; Vetsigian, 2017). The introduction of such feedbacks in plankton models is, however, a more recent line of research than in other microbial systems (Chen et al., 2018; Merico et al., 2014; Norberg et al., 2012; Smith et al., 2016). However, in most current models of microbial ecosystems, species traits do not evolve nor adapt over time. For example, current model projections of plankton community structure under future climate change scenarios assume that species have fixed traits (environmental preferences) and will not adapt to the new conditions (Dutkiewicz et al., 2013). The need to include adaptive dynamics in the next generation of microbial models is widely recognized (Irwin et al., 2015) and several important contributions have been made in this direction (e.g., Chen et al. (2018), Edwards and Steward (2018), Lomas et al. (2014), Merico et al. (2014), Norberg et al. (2001), Sauterey et al. (2017), Sauterey et al. (2015), Smith et al. (2016) and Williams and Lenton (2008)).

The ability to adapt to changes in resource concentration may be linked to mutations in genes that regulate cell size or shape, as well as the number and efficiency of membrane transporters (see Section “Uptake Machinery”). Likewise, the ability to adapt to environmental changes in temperature or irradiance may be linked to mutations in the genes that regulate biochemical reactions involved in catalytic efficiency or light harvesting capabilities. Eco-evolution also applies to social behaviour in microbes, such as cellular adhesion to form aggregates with collective functioning (Garcia et al., 2015) (see Section “Social Behavior in Microbes”). This long-term evolutionary capacity of microbes to adapt to changing environments or social contexts on decadal scales may be more predictive than short-term physiological responses (or acclimation) in determining the winners and losers under future climate change scenarios (Dutkiewicz et al., 2013). The absence in most models of mechanisms allowing the *adaptive radiation* of species-traits resulting from random mutations combined with natural selection implies that once a dominant species is established, it will remain unchanged and with no possibility to be unchallenged by newly created species (Dieckmann, 1999; Geritz et al., 1998) (i.e., resident phenotypes *versus* mutant phenotype PIP – see Fig. 10). Finding ways to include ecological evolution in models (e.g., evolutionarily singular strategies and/or trait-diffusion frameworks) is an active field of research (Chen et al., 2018; Doebeli, 2002; Fritsch et al., 2017; Szappanos et al., 2016). Adding eco-evolutionary dynamics to microbial models may help understand fundamental hypotheses of species evolution such as the “Red Queen Dynamics” (Bonachela et al., 2017). Theoretical models can help improve our understanding of ecological evolution by testing hypothesis about the conditions for adaptive evolution, the waiting time to adaptation, the duration of adaptive processes and the different characteristics of the emerging species (Gavrilets, 2004). These features are expected to depend on different evolutionary factors and parameters, such as the rates of migration and mutation, the strength of selection for local adaptation, population size, or the spatial structure of the population.

Several “ecological evolution” (eco-evo) frameworks for modelling Adaptive Dynamics (AD) of traits based on evolutionarily singular strategies (ESS) and pairwise invasibility plots (PIP) (Dieckmann, 1997; Dieckmann and Law, 1996; Geritz et al., 1998; Smith, 1982) or modelling Trait Diffusion (TD) based on solving the mean and variance of trait distributions (Norberg et al., 2001), were developed more than 20 years ago. These modelling frameworks for eco-evo are based on the notion of Dynamic Fitness Landscapes (DFL) that is rooted on the original concept of *adaptive landscapes* (Shpak, 2012; Wright, 1932) (see Figs. 11 and 12). Although the definition of the “fitness” metric is context dependent (Metz, 2018; Metz et al., 1992), for deterministic models the fitness of an ecotype under the local environmental conditions is usually measured as the biomass-specific growth rate (d^{-1}) of the population. DFL give the relationship between genotype and survival fitness for a given environmental condition (Loewe, 2016). The horizontal axes (independent variables) represent the *genotype space* (the set of all possible genotypes) and the vertical axis (dependent variable) represents the *genotype's viability* (probability of survival or growth rate) (see Fig. 12). Due to feedbacks between survival fitness and genotype frequency, the fitness landscape is not static but dynamic because of its density-dependency on gene frequencies, which vary through time (Doebeli et al., 2017; Mustonen and Lassig, 2009; Richter, 2013; Richter and Engelbrecht, 2014; Shpak, 2012). They also change in response to variations in the abiotic environmental conditions. Thus the original view of evolution along static fitness landscapes is now recognized to be misleading since evolution happens along

Fig. 10 Pairwise invasibility plots (PIP) and the classification of evolutionarily singular points (ESS). *[left-panel]* The horizontal axis defines the phenotype of the resident population given by the scalar value k_r of one trait (e.g., optimal temperature). The vertical axis defines the phenotype of a mutant population given by the scalar value k_m of the same trait. The invasion fitness λ_m (see Box 4) is defined as the specific growth rate (d^{-1}) of an initially rare mutant within local the environment (e.g., ambient temperature) where a resident population is well established. The resident population is assumed to be a demographic attractor in steady-state and therefore has $\lambda_r = 0$. Shaded areas represent the trait-space combinations (k_r, k_m) for which a rare mutant with phenotype or trait value k_m can invade a resident population consisting of individuals with phenotype or trait value k_r ; that is, the regions for which $\lambda_m > 0$. Clear areas represent the regions for which $\lambda_m < 0$, therefore where the rare mutant cannot invade the resident phenotype. The evolutionary process can be seen as a sequence of successfully established invasions, where the mutant phenotype k_m then becomes the new resident k_r . The strategy or trait value for which evolution can come to a halt are called *evolutionarily singular strategies* (ESS). Near such points the fitness landscape as experienced by a rare mutant is locally flat. ESS can be (i) a local fitness maximum representing a possible endpoint of evolutionary change; (ii) a local fitness minimum at which evolutionary branching can occur; or (iii) a degenerate case (these are without real-world significance). A given singular strategy can be evolutionarily stable (either convergent or non-convergent) or evolutionarily unstable (either convergent or non-convergent). *[right-panel]* The adaptive dynamics (AD) invasion function of a particular ecological system defines a PIP for resident and mutant phenotypes. When the invasion function is positive for a particular pair of phenotypes, the resident may be replaced by the invading mutant. Intersections of the invasion function's zero contour line with the 45° line indicate potential evolutionary end-points. Knowing the slope of the contour line at these singular points suffices to answer four separate questions: (1) Is a singular phenotype immune to invasions by neighboring phenotypes? (2) When starting from neighboring phenotypes, do successful invaders lie closer to the singular one? (3) Is the singular phenotype capable of invading into all its neighboring types? (4) When considering a pair of neighboring phenotypes to both sides of a singular one, can they invade into each other? Picture credits: © Dieckmann, U., 1997. Can adaptive dynamics invade? Trends in Ecology & Evolution 12 (4), 128–131.

dynamic fitness landscapes (Mustonen and Lassig, 2009). The basic idea of evolutionary ecology is that ecotypes in a community differ in fitness because their different genotypes make them suitable for different environments (Doebeli et al., 2017). This allows the community to track environmental changes and avoid catastrophic collapse (see Fig. 11). The relationship between genotype and fitness is mediated by the phenotype. Therefore, the conceptual framework of DFL can be applied to discrete genetic sequences (i.e., number of loci and number of alleles per locus) that define the genotype, as well as to continuous quantitative traits (e.g., organism size, optimum temperature, etc.) that define the phenotype. Either way, the population evolves to a state where its average fitness is maximized (Nagylaki, 1992). That is, the divergence of populations along DFL under the joint action of different selection pressures results in the evolution of traits and, ultimately, speciation (Geritz et al., 1997; Ostman et al., 2014). The presence of competitive trade-offs for the uptake of resources has been shown to lead to adaptive evolution and the gradual establishment of microbial ecotypes (Gudelj et al., 2007; Ostman and Adami, 2013; Ostman et al., 2014).

More broadly, the flows of genetic material in microbial populations and communities can be classified as *horizontal*, i.e., moving from one organism to another that is not its offspring; and *vertical*, i.e., moving from one generation to the next (see Fig. 13). Horizontal gene transfer is widespread among bacteria and archaea, because these prokaryotic microorganisms lack internal nuclear membranes to contain and protect their DNA. Thus, prokaryotes rapidly acquire genes from other prokaryotes and even from eukaryotes. Many researchers have therefore abandoned the term *species* and instead refer to different prokaryotic taxa as *ecotypes*. Cohan originally defined an ecotype as: “a set of strains using the same or very similar ecological niches, such that an adaptive mutant from within the ecotype outcompetes to extinction all other strains of the same ecotype; an adaptive mutant does not, however, drive to extinction strains from other eco-types” (Cohan, 2001). The stable ecotype model (SEM) of bacterial speciation (Cohan, 2006) thus gives a prominent role to natural selection regarding the formation and maintenance of separate genetic clusters (see Fig. 14) (Shapiro et al., 2012). In contrast, most gene transfer is vertical for eukaryotic microorganisms, such as green algae,

Fig. 11 Non-adaptive evolution (a) vs. adaptive evolution (b) of a simulated ecotype on a fitness landscape for a two-dimensional genotype space. The red genotype is well-adapted because it is located on the fitness peak of this starting Dynamic Fitness Landscape (DFL). A change in the local environment shifts the fitness peak, so that the red genotype is no longer of high fitness (bottom). (a) Abrupt (or fast) environmental changes requires the non-adaptive exploration (any direction) of the neutral part of the landscape. (b) Gradual (or slow) environmental changes allow for Adaptive Evolution (AD) through small mutation steps (hill climbing) as defined by the pairwise invasibility plots (see Fig. 10). Adaptive evolution of complex innovations through stepwise metabolic niche expansion. *Nature Communications* 7, 11607. doi:10.1038/ncomms11607.

Fig. 12 Dynamic Fitness Landscape (DFL) in a 2D genotype space showing two peaks. Fitness peaks for a given genotype depend on the local environment, but environmental conditions (*e.g.*, nutrient concentration) may also be affected by population dynamics (*i.e.*, gene frequencies) over time so there is a feedback between fitness and organisms. Environmental changes can trigger perpetual changes in fitness, resulting in a constant need for adaptation. Picture credits: © Loewe, L., 2016. Systems in evolutionary systems biology. In: Kliman, R.M. (Ed.), *The Encyclopedia of Evolutionary Biology*, vol. 4. Oxford Academic Press, Elsevier, pp. 297–318. doi:10.1016/B978-0-12-800049-6.00184-0.

Fig. 13 Genes and associated traits can diffuse (a) horizontally, independent of any genetic relationship among the organisms (red dots denote a gene of interest moving between bacterial cells), and (b) vertically, *i.e.*, through inheritance from generation to generation, as denoted here for phytoplankton reproducing to produce offspring of differing size.

fungi and protozoa, because they have nuclear membranes isolating their genetic material. Many ecological models represent different ecotypes and strains. However, it has also proven useful to develop models and analyse data in terms of the *probability distribution of traits* using continuous functions, without explicitly representing ecotypes or strains (Follows and Dutkiewicz, 2011; Norberg, 2004). Such models have been applied to population genetics and evolution (McGill and Brown, 2007), and recently for understanding biogeographical distributions and Biodiversity Ecosystem Function (BEF) relationships of marine plankton (Chen et al., 2018; Smith et al., 2016) on ecological timescales (see Section “Biodiversity and Ecosystem Functioning”).

Both horizontal and vertical gene flows generate genetic (and hence phenotypic) variations, and thus in effect they “diffuse” trait values through populations and communities. This maintains microbial biodiversity and sustains the adaptive capacity of microbial ecosystems. These trait variations are then *filtered* by competition and environmental factors to shape the compositions of populations and communities, and ultimately by ecological evolution to determine the course of evolution. The Trait Diffusion (TD) framework (Merico et al., 2014) simulates the diffusion of trait values through successive generations, as a result of various processes such as vertical gene transfer and/or de-novo mutations. TD can thus be viewed as a mean of representing in microbial models the maintenance of species-trait diversity *via* endogenous mechanisms. These mechanisms of adaptive evolution can include mutation or rapid evolution (Yoshida et al., 2003), which alter the genotype; as well as trans-generational phenotypic plasticity, which is independent of changes in the offspring genotype. The different ecotypes would evolve driven by the three major factors controlling evolutionary dynamics of microbes: random mutation, genetic drift, and natural selection. Therefore, the TD approach gives a simple yet powerful mathematical framework to parameterize these eco-evo factors without the need to simulate them explicitly (Smith et al., 2016). TD assumes that the rate of trait diffusion is directly proportional to growth rate and its derivatives. This framework could readily be applied to model the effects of trait diffusion on the eco-evolutionary dynamics of other eukaryotes (*e.g.*, fungi) and possibly also with some modification of prokaryotes. However, TD does not represent horizontal trait diffusion, which can dominate the flow of genes and traits among prokaryotes migrating within spatially heterogeneous environments (Niehus et al., 2015). Such migration is likely common given that micro-scale variability is commonly observed (Section “Micro-Scale Variability”). Rates of horizontal trait diffusion must depend on the presence of other organisms and phages (viruses) as well as growth rates.

Currently the TD framework is well developed for one trait (*e.g.*, cell size linked to nutrient uptake strategy); that is, for one-dimensional (1D) dynamic fitness landscapes of ecological evolution. However, the dimensionality of DFL is probably very large for most organisms, with different traits being important along different environmental gradients. For procaryotic microbes, two major environmental gradients dominating the ecology and evolution of the ecotypes are the concentration of resources (*i.e.*, uptake strategy) and the temperature of the environment (*i.e.*, thermal tolerance). For eukaryotic phytoplankton, a third environmental gradient is the solar irradiance (*i.e.*, light harvesting and photoprotection). Therefore, the simulated microbial ecotypes should be able to evolve by varying the value of their optimal traits (*e.g.*, N_{opt} , T_{opt} , I_{opt}) under an hypervolume of environmental conditions (see Fig. 9). Dynamic fitness landscapes are variable in space and time due to changes in the environmental conditions. Therefore, the rate of trait-diffusion (*i.e.*, a mathematical parameterization of the genotype mutation rate) of the microbes should be sufficiently fast to track the environmental changes, in order to capture the adaptive capacity of the population or community of interest. Furthermore, even in relatively stable environments, fitness landscapes can change with the genetic state (*i.e.*, ecotype frequencies) of the population as a result of density-dependent selection (Gavrilets, 2004). The evolutionary trajectories are expected to follow the changes in DFL resulting from (i) variability of the environment and (ii) inter-specific competition. Basically each population should try to “climb” the fitness gradient (including both biotic and abiotic factors) in order to maximize their

Fig. 14 Ecological differentiation in recombining microbial populations leading to evolutionary branching of two distinct ecotypes. (A) Example genealogy of neutral marker genes sampled from the community at different times. (B) Underlying model of ecological differentiation. Thin gray or black arrows represent recombination within or between ecologically associated populations. Thick colored arrows represent acquisition of adaptive alleles for red or green habitats. chances of survival (*i.e.*, attain the fastest possible biomass-specific growth rate of the population) under any given environmental condition. The resulting trajectories may be the result of a “tug of war” between two opposite directions: *convergent evolution* to maximize performance under the current environmental conditions and *divergent evolution* to avoid strong competition for a limited set of resources among phenotypically similar populations (Darwin, 1859).

Further work is needed to develop improved models and better understand the roles of trait diffusion in the eco-evolutionary dynamics of microorganisms. One particularly promising area is modelling horizontal trait diffusion and its effects among prokaryotes, which are important in epidemiology, the micro-biome of the human gut, and many commercial applications. Trait diffusion also needs to be considered in the context of the Complex Adaptive Systems (CAS), which define systems with the capacity of *self-organization* where (1) patterns emerge from the interaction among its components, and (2) these interactions are in turn affected by the patterns they produce (*i.e.*, there is feedback between the system’s components and its emergent properties)

(Holland, 1992; Levin, 1998). Microbial ecosystems are good examples of CAS when organisms migrate within spatially heterogeneous environments (Norberg, 2004) (Section “Micro-Scale Variability”). Spatially explicit CAS models yield unexpected dynamics, and even without considering TD have already given new insights concerning the evolution of cooperation, restraint (Werfel and Bar-Yam, 2004), group selection and the meaning of fitness (Goodnight et al., 2008). Spatial heterogeneity is expected to be especially important in microbial communities in which mobility is limited, as for instance in soil-dwelling microbiomes where variability in the porosity of the soil constrains the diffusion of the different molecules that are present in the environment (see Section “Micro-Scale Variability”).

Biodiversity and Ecosystem Functioning

Unveiling the relationship between biodiversity and ecosystem functioning is one of the major goals of ecological theory (Duffy et al., 2007; Hooper et al., 2005; Thompson et al., 2012), and it is becoming increasingly important in microbial systems (Glockner et al., 2012; Smith et al., 2016; Vallina et al., 2017). The simplest measure of biological diversity is the number of species that are present in a given place, but diversity can be measured using many indices and scales (Tuomisto, 2010; Whittaker et al., 2001). Species richness and the Shannon index (Shannon, 1948) are among the most commonly used due to their simplicity. However, these metrics do not always have a direct translation to *functional diversity* – from the point of view of ecosystem functioning, rather than the richness per-se it is the species identity and role that matters, both related to the species traits and trade-offs (Vallina et al., 2017). Scale is also an essential component of ecological theory because the response of dependent variables can change across spatial and temporal scales (Levin, 1992). There are three main terms for measuring biodiversity over spatial scales at a given time (snap shot): alpha, beta, and gamma diversity (Whittaker, 1972). *Alpha diversity* represents the mean diversity of species within a focal ecosystem or study region and is usually computed as the average value of the local species richness at each niche, habitat or site that the ecosystem contains. *Beta diversity* refers to the diversity of species that are unique to each habitat of the ecosystem and thus provides a measure of compositional heterogeneity. Finally, *gamma diversity* represents the total integrated diversity of the ecosystem from all habitats and thus provides a measure of its overall diversity.

Most microbial communities are important for ecosystem functioning, in particular soil microbial communities; plant-associated microbiomes (both microbes living within the roots or attached to them) (Loreau, 2010b); and planktonic communities, either bacteria (Fuhrman, 2009) or micro-algae (Litchman et al., 2015a). Since these habitats can have different sizes and the geographical limits among them are diffuse, there is no consensus on what spatial scales are the most appropriate to quantify alpha diversity. The suggestion is that it can be measured using habitats or sites of any scale that are delimited just for the purpose of analysis. Beta diversity can then be computed as the ratio between gamma over alpha diversity (Whittaker, 1972). These three definitions of biodiversity are also equally applicable over temporal scales at given location (focal point), or mixing space and time in the analysis. For example, the shape of the productivity-diversity relationship (PDR) for marine unicellular algae (*i.e.*, phytoplankton) at the scale of the global ocean using alpha diversity of species richness has been observed to be unimodal, with diversity peaking at intermediate levels of productivity (Irigoien et al., 2004). Numerical simulations showing the same global pattern when looking at weekly-averaged data suggested that predator-mediated coexistence by selective feeding (*i.e.*, killing-the-winner, see Section “Ecological Selection and Community Assembly”) explains the positive slope at low nutrient supply, while transient competitive exclusion explains the negative slope at high nutrient supply of this unimodal PDR curve (Vallina et al., 2014a).

Diverse communities are often more efficient in resource exploitation than single species communities and there is no a-priori limit to the total number of species (increasing the packing and elaboration of axes of the niche hyperspace) (Loreau, 2010a). This also applies to temporally-variable environments through local selection and dominance of the most efficient ecotypes. For example, higher diversity of thermal preferences has a positive effect on ecosystem functioning on a seasonal basis because it leads to *niche complementarity* of the species, which allows covering the whole temporal gradient in temperature. Likewise, a higher diversity of uptake strategies has a positive influence on ecosystem functioning through a *sampling probability* effect: the more uptake strategies are potentially available, the higher the chance of sampling a faster-growing strategy (Hooper et al., 2005; Tilman et al., 1997). The stability of aggregate ecosystem properties like total production or biomass has thus been suggested to increase with species diversity either through functional redundancy or functional complementarity (de Mazancourt et al., 2013). Species are redundant when they occupy the same environmental niche and fulfill the same functional role, and are complementary when they occupy different environmental niches within the same ecosystem and fulfill different functional roles (Loreau, 2010a). Functional redundancy helps sustain ecosystem functioning in the face of species extinctions through the replacement of species with similar ones, while functional complementarity decreases the temporal variance of aggregated properties (*i.e.*, increases the stability at the community level) through the species asynchrony with environmental variability (Vallina et al., 2017). Different species that have distinct ecological niches would respond differently to environmental changes, leading to an asynchrony of individual population dynamics (Loreau and de Mazancourt, 2013). Asynchronous responses of the populations will thus have a “buffering effect” on aggregate properties, leading to the *insurance hypothesis of biodiversity* for ecosystem functioning (Yachi and Loreau, 1999). This is a major prediction of niche theory regarding biodiversity and ecosystem functioning (BEF) that seems to be well supported with observational data for terrestrial plants (Loreau, 2010a) and freshwater phytoplankton (Ptacnik et al., 2008).

Neutral theory (see Section “Ecological Selection and Community Assembly”), on the other hand, states that coexisting species are ecologically equivalent and therefore the rate of competitive exclusion becomes infinitely slow (Hubbell, 2001). Thus, in the view of neutral theory, diversity has no functional consequences (Loreau, 2010a). Under this modelling framework, the dynamics of

an isolated microbial community then becomes a slow random drift to extinction due to the stochastic probability of both birth and death processes, leading to transient non-equilibrium coexistence. However, for non-isolated communities this random drift can be counterbalanced by the immigration by dispersal into the local community of new species coming from an external pool of microbial communities or metacommunity, leading to permanent coexistence. The identity of species continuously change but the microbial community properties such as the species abundance distribution (SAD) remains invariant. The main drawback of neutral theory for microbial ecosystem modelling is that there is a large body of evidence that most species in natural ecosystem are not functionally equivalent – many studies have shown that microbial ecotypes have deterministic niche differences and that ecological displacements by competitive exclusion are common (Coyte et al., 2015; Follows and Dutkiewicz, 2011; Ghoul and Mitri, 2016; Litchman and Klausmeier, 2008). In addition, neutral theory in its current form is seen as incompatible with niche theory (Loreau, 2010a).

There is also the middle-ground possibility that both theories (niche and neutral) may be partially correct and be in fact complementary to explain microbial community assembly. Observational data show that rank-abundance distributions (RAD) of microbial communities are often highly skewed, with a few dominant ecotypes and a long tail of low abundant ecotypes that form the so-called *rare biosphere* (Fuhrman, 2009; Pedros-Alio, 2006, 2012; Ser-Giacomi et al., 2018). The tail of rare ecotypes is thought to be the result of bottom-up controls (being in sub-optimal environments for growth) and top-down killing-the-winner processes (being subject to relatively smaller mortality) (Pedros-Alio, 2006). Global ocean simulations resolving many ecotypes of phytoplankton based on niche theory, for example, also show the same pattern (Follows and Dutkiewicz, 2011). This suggests that: (i) the few dominant ecotypes of the RAD are in their optimal environmental niches and thus are outperforming most of the ecotypes by ecological selection; (ii) the many rare ecotypes of the RAD are far from their optimal niches and have been probably recruited through immigration by dispersal; and (iii) within either category but particularly for the long tail of rare ecotypes, coexistence is probably happening because ecotypes have very similar fitness and thus can be viewed as close to *competitively neutral*. Eventually, environmental conditions may change and some rare ecotypes could then become dominant (and *vice-versa*) (Pedros-Alio, 2006). Therefore, the rare biosphere of microbes can be seen as a “seed-bank” of biodiversity and way to store *potential* ecosystem functioning (Zorach and Ulanowicz, 2003).

Under temporally varying and/or spatially heterogeneous habitats, keeping a rare biosphere of microbes waiting to become dominant when conditions change may thus lead to what is known as *overyielding*. Overyielding occurs when the production of a multi-species community is higher than the production of each of its species as a mono-culture. Niche differentiation and functional complementarity are thought to lead to overyielding production on microbial ecosystems. There are two major mechanisms by which biodiversity can lead to overyielding: *sampling probability* effect and *niche complementarity* effect (for details see Fig. 2 in Hooper et al., 2005). These mechanisms explain the BEF response curve of simulated microbial communities such as phytoplankton when the species functional diversity is given by their range of uptake strategies and temperature tolerances (Vallina et al., 2017). An increase in the range of nutrient concentration niches (N_{opt}) leads to sampling probability, while an increase in the range of temperature niches (T_{opt}) leads to niche complementarity. Note that the BEF response curve for each of these mechanisms is different: sampling probability has no effect on the maximum values of the ecosystem functioning indicators (e.g., productivity and stability), while niche complementarity increases both the maximum and minimum values of these indicators (see Fig. 15). These BEF responses for simulated microbes agree well with the general BEF curves predicted for terrestrial plants under theoretical scenarios of sampling probability and niche complementarity (Tilman et al., 1997).

Regarding *niche complementarity*, a microbial ecosystem with a spatial environmental gradient of temperature will be more productive if all its temperature niches are being occupied simultaneously by locally adapted ecotypes. This is because the *fundamental niches* for temperature (negative-skew gaussian bell curves) are *closed at both ends* and thus a single ecotype will generally not be able to cover (i.e., survive at) the whole range of ambient temperatures under a mono-culture (see Fig. 9, upper-center). Regarding the *sampling effect*, a microbial ecosystem with a spatial environmental gradient of nutrient concentration will be more productive if *at least* one fast growing ecotype is present in the community. That is, there is no need to have a diversity of uptake strategies (i.e., affinity-adapted *versus* rate-adapted) simultaneously as long as one rate-adapted (i.e., opportunist) species is present. This is because the fundamental niches for nutrients (Michaelis-Menten curves, see Fig. 2) are *not closed on the upper side* since high nutrient concentrations are (usually) not harmful for growth, and thus a single ecotype will be able to cover (i.e., survive at) the whole range of resource concentrations under a mono-culture (see Fig. 9, upper-left). In this case, the probability of sampling at least one rate-adapted ecotype increases with biodiversity. Therefore, having a high diversity of uptake strategies translates into having a higher chance of having a highly productive microbial community. The effect on ecosystem functioning of diverse uptake strategies is thus not the result of functional complementarity but the result of sampling probability (Tilman et al., 1997). The concept of *thermal niche* and *nutrient niche* are therefore quite different from the point of view of BEF in microbial communities because they lead to different mechanisms of overyielding (Hooper et al., 2005). The concept of *irradiance niche* for photo-autotrophic microbes falls somewhere in the middle of these two extreme categories if there is photo-inhibition at high solar radiation (see Fig. 9, upper-right). The same reasoning applies to temporal environmental gradients (see Fig. 15) (Vallina et al., 2017).

Micro-Scale Variability

Micro-scale variability plays a central role in determining the functioning of microbial communities and the various processes that they govern. It is especially important in contexts in which, due to limited mobility, cells explore a limited range of environments

Fig. 15 Phytoplankton annual average community-level primary production ($\text{mmol C m}^{-3} \text{ d}^{-1}$) and its temporal stability (inverse of the coefficient of variation normalized by its maximum value; n.d.) as a function of the diversity in thermal preferences (left panels) and the diversity in nutrient uptake strategies (right panels). The red dots correspond to the median value of the distribution. The gray shaded area spans from the minimum to the maximum value of the distribution. Increasing the diversity of thermal preferences of the phytoplankton community leads to a strong increase in the median, minimum and maximum value of the community-level production and its temporal stability over a seasonal cycle. Increasing the diversity of uptake strategies of the phytoplankton community leads to a strong increase of only the minimum value of the community-level production and its temporal stability over a seasonal cycle, to a weak increase of the median value, and has no effect on the maximum values of the distribution. Picture credits: © Vallina, S.M., Cermeno, P., Dutkiewicz, S., Loreau, M., Montoya, J.M., 2017. Phytoplankton functional diversity increases ecosystem productivity and stability. *Ecological Modelling* 361, 184–196. doi:10.1016/j.ecolmodel.2017.06.020.

and interact mostly with individuals in their closest neighborhoods. Nano- and micro-scale variability are well appreciated features of soil ecosystems (Fierer, 2017; Kuzyakov and Blagodatskaya, 2015). In terrestrial ecosystems, bacterial distributions in the soil show a high degree of clustering, due to the combined effect of extrinsic (e.g., pore size, availability of organic matter) and intrinsic factors (e.g., reproductive pair correlations) (Raynaud and Nunan, 2014). Regardless of the environmental conditions in which they thrive, bacterial biofilms are a paradigmatic example in which short-scale variability is well-known to be of paramount importance. Biofilms are dense and highly diverse communities in which cells remain encased in a secreted polymer matrix that holds them together and hence reduces their mobility dramatically. They are central for global scale processes, such as biogeochemical cycling, play a central role in the interaction between bacteria and multicellular organisms, and provide a myriad of potential biotechnological applications (Fux et al., 2005; Halan et al., 2012; Paerl and Pinckney, 1996). However, the contribution of biofilms to each of these processes is usually controlled by the secretion of different metabolites, whose efficiency is strongly determined by the spatial arrangement of the different species within the matrix (Nadell et al., 2016). Due to the importance that spatial structure has for biofilm functioning, several models have attempted to understand the means by which individual cells interact among them and with the environment during biofilm proliferation as well as the ecological and evolutionary implications of the nascent patterns of spatial variability (Nadell et al., 2010; van Gestel et al., 2015). Most of these models rely on individual-based approaches, in which each cell is treated as a discrete entity (Xavier and Bassler, 2005; Kreft et al., 2001; Martínez-García et al., 2018), but frameworks based on reaction-diffusion descriptions of the growth dynamics have been proposed as well (Horn and Lackner, 2014).

Less obvious has been the existence of micro-scale patterns of spatial variability in environments where microbes are subject to external mixing forces, such as the aquatic environment. Over 30 years ago, however, such microscale patchiness in the distributions of organic matter, bacteria, and other microorganisms was observed and appreciated as an important feature of marine ecosystems and the biogeochemical cycles that they mediate (Azam et al., 1994). More recently, patchiness in the distribution of marine phytoplankton has been widely observed and confirmed to impact the productivity of simulated plankton ecosystems (Brentnall et al., 2003; Mandal et al., 2014). Spatial heterogeneity of microbial distributions in aquatic systems arises from the clustering of organisms (see Fig. 16). Also, in the presence of potential mixing forces such as external flows and micro-scale eddy stirring, organisms can cluster in certain turbulent regimes (see Fig. 17). More generally, environmental heterogeneity at larger scales has long been known to impact ecological dynamics and enhance biodiversity by providing distinct environmental niches physically separated (e.g., d'Ovidio et al., 2010; Levy et al., 2014). Micro-scale aggregates (<1 mm) of particulate organic matter, phytoplankton, and bacteria constitute microbial hotspots in the ocean (Azam et al., 1994), with distinct environmental niches that are important for aquatic ecology and biogeochemistry. Furthermore, because plankton undergoing limited migration (incomplete

Fig. 16 Many theoretical models were first developed assuming (A) homogeneous environmental conditions as denoted here for the distribution of bacterial cells and their growth substrate (blue dots). (B) Now more and more models are accounting for spatial heterogeneity, as depicted here for a patchy distribution of bacteria and their substrate. Environmental heterogeneity is typical of many natural environments and in many cases yields substantially different predictions of both ecological and evolutionary dynamics.

Fig. 17 Stirring of a nutrient patch and response of chemotactic bacteria within a domain of ≈ 0.5 m length using direct numerical simulations (DNS). As a nutrient patch is stirred by a turbulent flow (top row, showing nutrient concentration C), chemotactic bacteria respond by accumulating within nutrient filaments (bottom row, showing concentration of motile bacteria B_M), thereby enhancing their uptake. Picture credits: © Taylor, J.R., Stocker, R., 2012. Trade-offs of chemotactic foraging in turbulent water. *Science* 338 (6107), 675–679. Available at: <http://science.sciencemag.org/content/338/6107/675>.

mixing) in aquatic environments constitute Complex Adaptive Systems (CAS), a CAS modelling approach for simulating the biodiversity and adaptive dynamics of such systems has recently been developed (Norberg, 2004). Although the emphasis was given on larger spatial scales, the same principle applies for migration between distinct micro-environments.

The ubiquity of micro-scale variability suggests that CAS dynamics are common in the eco-evolutionary dynamics of microorganisms. Also, recent modelling studies have revealed novel insights into the complex eco-evolutionary dynamics of microorganism in spatially heterogeneous environments. Evolution and maintenance of social cooperation, restraint, and altruism can be explained by considering eco-evolutionary dynamics with migration under environmental heterogeneity (Werfel and Bar-Yam, 2004) (see Section “Social Behavior in Microbes”). A similar model predicted complex dynamics for group selection (Goodnight et al., 2008). Migration between distinct habitats enhances substantially the degree to which horizontal gene transfer impacts the genetic diversity and evolution of prokaryotes (bacteria and archaea) (Niehus et al., 2015). Phytoplankton distributions in coastal waters have also been shown to display great vertical heterogeneity or intermittency, with layers of increased fluorescence and concentration, probably resulting from a fine balance between layer formation and destruction through mixing (Prairie et al., 2011). These peaks or anomalies in concentration over the background value can have disproportionate effects on the biological dynamics. They are usually modelled using the same approach employed in turbulence theory (Mandal et al., 2016).

Fractal patchiness at the micro-scale can occur when motile phytoplankton are exposed to turbulent flow, leading to increases in local concentration of an order of magnitude. They are the result of a balance between cell motility and fluid shear (Durham et al., 2013). Motile bacterioplankton can exploit ephemeral micro-patches of resources through chemotaxis in turbulent environments (see Fig. 17). This gives them an advantage over non-motile competitors, albeit subject to a trade-off against the energetic cost of locomotion. There exists therefore an optimal swimming speed of $\approx 60 \mu\text{m s}^{-1}$ for standard marine conditions (Stocker and Seymour, 2012; Taylor and Stocker, 2012). Compared to typical plankton ecosystem models based on mean-field (background) concentrations, the newly developed models that account for the micro-scale variability (anomalies) in the distributions of plankton and nutrient concentration have yielded substantially different simulated spatio-temporal patterns of biomass and productivity at macroscopic scales (Mandal et al., 2016). These models have also predicted that micro-scale variability may enhance trophic transfer and potentially also biodiversity (Priyadarshi et al., 2017).

The distribution of micro-scale aggregates can be represented either explicitly as in agent- or individual-based models (Goodnight et al., 2008; Werfel and Bar-Yam, 2004), by direct numerical simulations (DNS) of turbulence at high spatial resolution (Taylor and Stocker, 2012), or statistically in ecosystem models at low spatial resolution by decomposing the concentration fields into mean and fluctuating parts. The last approach is analogous to the Reynolds decomposition employed widely in fluid dynamics (Mandal et al., 2016; Mandal et al., 2014; Priyadarshi et al., 2017). Accounting for micro-scale variability compounds the already formidable challenge of modelling the combined effects of ecological dynamics and physical transport by advection and diffusion (Mandal et al., 2016), which are relevant to many microbial systems. Future studies that better account for micro-scale variability have much potential to yield new insights into the eco-evolutionary dynamics of microorganisms. Remaining challenges include developing models that are both sufficiently robust for application over wide environmental gradients (e.g., in 3-D models of ocean circulation and marine ecosystems) and computationally efficient enough to be practically useful for simulation studies. Promising approaches have begun to incorporate the effects of heterogeneous environments as “interaction structure” within the compact Adaptive Dynamics equation that is already widely used to model eco-evolutionary trait dynamics (see Section “Ecological Evolution and Community Adaptation”) (Allen et al., 2013b).

Social Behavior in Microbes

Microbes very often coordinate their behavior with each other in order to perform several tasks, such as foraging, dispersal, reproduction, or nutrient acquisition (Crespi, 2001). This vast variety of collective behaviors, together with their lab manageability, fast evolution, and the various possibilities of molecular and genetical manipulations, have turned microbes into a recurrent model to investigate social behaviors and inspired many theoretical models. Microbial collective behaviors are very often controlled by the secretion of substances to the extracellular medium, named exo-products. Exoproducts may serve to coordinate behavioral synchronization *via* quorum-sensing communication (Czárán and Hoekstra, 2009; Miller and Bassler, 2001), but they can also establish different types of ecological interactions among cells. For instance, mutualistic interactions may arise in mixed cultures in which each species benefits from the exoproducts of its partner in the mix (cross-feeding); antagonistic interactions have been also observed, as represented by the different forms of chemical warfare that facilitate the elimination of competing individuals in some bacterial species (McNally et al., 2017; West et al., 2007) (see Fig. 18(a)).

Especially interesting from an evolutionary perspective are cooperative interactions, actions that incur in a cost for the executor and whose benefit is shared with other individuals in the population. A paradigmatic example in which such dilemma arises is the synthesis of public goods, exoproducts that are costly to produce and benefit both the producer and its neighbours (see Fig. 18(a)). In a well-mixed population of public-good producers and non-producers, every individual interacts with each other, and therefore the payoffs for each species due to public-good production are:

$$f_{NP}(N_P) = rc(N_P/N) \quad (54)$$

$$f_P(N_P) = f_{NP} - c \quad (55)$$

Fig. 18 (a) Cell secretions may establish different types of ecological interactions. Mutualistic interactions, as represented by cross-feeding, appear when each of the species in the mix benefits from the secretions of the other species in the mixes. Antagonistic interactions are represented, for instance, by chemical warfare in bacteria, in which exoproducts kill competing cells. The costs associated to the actor (green cell) in these behaviors may be just a reduced growth rate due to allocation of resources into chemical production, but sometimes the release of the substances requires cell death. Cooperative behaviors may be classified in two major categories depending on whether the actor also receives a benefit or only pays a cost without receiving a direct fitness benefit. Public good production is an example of the former, while persistent cells constitute an example of the latter (see main text for a detailed explanation of both behaviors). The existence of these non-growing phenotypes alleviates the competition for resources, which favors the growth of conspecifics. (b) The life cycle of *Dictyostelium discoideum* is an example of division of labor in microbes. Starvation triggers the coordinated aggregation of free-living amoebae and the beginning of a developmental program that culminates with the formation of a fruiting body. Within the fruiting body, about 80% become dormant spores, whereas the other 20% facilitates spore dispersal by forming a stalk of dead cells. (c) Biofilms present a huge diversity of social behaviors, ranging from the secretion of exoproducts that establish mutualistic, competitive or cooperative interactions, programmed cell death, to quorum-sensing, to division of labor.

where the subscripts NP and P stand for non-producers and producers respectively. N_P is the number of producers within the population of total size N , r gives the benefits provided by the public good, and c is the cost of the cooperative behavior (i.e., the investment in the public good). Therefore, the total revenue of the public good depends on the number N_P of producers, how much c they invest in the production, and the growth multiplication factor r of the public good. Additionally, each individual obtains an equal share from this total production, regardless of whether it contributed to the production or not, but producers have to cope with the additional production cost. In such simplified scenario, non-producers will always outcompete producers because they get their shared benefit of the cooperative behavior without bearing its cost, and any initial mix of species will converge to an extinction of cooperators. This result, hence, poses an interesting *evolutionary dilemma* that can be summarized in two questions. First, why would an individual decrease its own fitness to confer fitness benefits on other individuals? And second, what are the mechanisms that stop the invasion of non-cooperative mutants (represented here by non-producers) and avoid the extinction of cooperation?

Several models have proposed mechanisms that could turn cooperation evolutionarily stable (see Section “*Ecological Evolution and Community Adaptation*”) and solve this dilemma: (1) the increase in population size due to cooperation makes the system more robust against extinctions induced by demographic fluctuations (Constable et al., 2016); (2) individuals that transiently neither execute nor benefit from the cooperative behavior are resistant to mutants and provide a pool to recover cooperation (Hauert et al., 2002); (3) the partial privatization of the benefits of cooperation by cooperators (Gore et al., 2009; Jin et al., 2018); (4) the effect of external forces, such as environmental flows (Drescher et al., 2014; Uppal and Vural, 2018); and (5) any form of assortment that makes cooperators more likely to interact with other cooperators in game-theoretic frameworks (Nowak, 2006). Some of the mechanisms to achieve assortment are: the existence of a spatial structure in the environment that, combined with individual limited mobility or cell properties such as adhesion and/or directed movement, keeps related cells together (Allen et al., 2013a; Nowak and May, 1992; Tamita et al., 2009); recognition of cooperators and non-cooperators in order to choose the partner in the interactions (Antal et al., 2009; Pacheco et al., 2006); reciprocity *via* individual reputation or/and memory in the interactions

(Axelrod and Hamilton, 1981; Nowak and Sigmund, 2005); or multilevel selection, which considers that different selective pressures acting at the individual and the group level favor groups dominated by cooperators (Keller, 1999; Traulsen and Nowak, 2006). However, these models very often oversimplify the ecological context in which interactions occur, as well as the possible existence of eco-evolutionary feedbacks that emerge due to the rapid evolution of microbes and that can reshape their ecology (see Section “Ecological Evolution and Community Adaptation”) (Estrela et al., 2018; Tarnita, 2017). The necessity of modelling the ecological context and eco-evolutionary feedbacks is supported by numerous experimental studies. For instance, the cooperative nature of Pyoverdine production (an iron-chelating molecule hypothesized to be a public good) in *Pseudomonas* strongly depends on the environmental conditions in which strains evolve (Zhang and Rainey, 2013). Hence, any sociobiological label assigned to these secretion behaviors is only meaningful when posed in the proper ecological context, which should be recognized in any modelling framework (Estrela et al., 2018; Tarnita, 2017).

Beyond the production and release of public goods and other exoproducts, cooperation relates to division of labor, whereby individuals in a population specialize in different tasks. This leads to fitness differences across cells, as illustrated by cell differentiation in *Dictyostelium discoideum* fruiting bodies: upon starvation, single-living cells aggregate and develop a multicellular fruiting body, in which only a proportion of cells become spores and eventually reproduce, while the rest die to form a stalk (see Fig. 18(b)). Other examples of cooperation are provided by persisters, cells that exist in a quiescent non-growing state, or programmed cell death. In both cases, the existence of non-growing phenotypes alleviates the competition for resources, which favors the growth of conspecifics (West et al., 2007). These fitness differences between phenotypes that are specialized in different tasks depend on the ecological context in which populations thrive, which emphasizes the necessity of developing more comprehensive models that include a description of the environmental dynamics. Persister cells, for instance, while growing slowly, show antibiotic resistance and could thus outcompete fast-growing susceptible phenotypes in antibiotic-rich environments. Considering that persistence is acquired through a reversible phenotypic switch (Balaban et al., 2004), a model that explicitly describes fluctuations in the concentration of antibiotics in the environment has shown that, rather than a cooperative behavior, persistence could constitute an adaptation that is tuned in stochastic environments by the statistical properties of changes in antibiotic concentration (Kussell et al., 2005).

Finally, all the behaviors discussed in this section frequently occur simultaneously and are hard to disentangle from each other. An example of such complex scenarios are biofilms, conglomerates of cells that often belong to hundreds of different species and grow attached to surfaces, subject to external flow stresses (Drescher et al., 2014; Kempes et al., 2014; Martínez-García et al., 2018; Persat et al., 2015) (Fig. 18(c)). Division of labor has been reported in *Pseudomonas* biofilms, with some phenotypes specializing in biofilm growth and others in dispersal. Quorum-sensing plays an important role in initiating and structuring the biofilm, as well as in regulating the secretion of several exoproducts. Cell cooperation is crucial in the secretion of the extracellular matrix that holds cells together, and in the production of numerous public goods that regulate various aspects of biofilm progression and functioning. The secretion of other substances, such as antibiotics or bacteriocins, establishes competitive interactions between cells. And, finally, programmed cell death aids in structuring the biofilms (see Nadell et al., 2016; West et al., 2007 for a review). Importantly, due to their reduced mobility, biofilm-dwelling bacteria mainly interact with cells in their local environment (see Section “Micro-Scale Variability”). This makes biofilms a very appropriate system to develop theoretical frameworks that couple ecological factors and the various forms of assortment that influence the outcome of social interactions (Martínez-García et al., 2018; Nadell et al., 2016).

Acknowledgements

We thank Jim P. Grover and Michel Loreau for their comments on an earlier version of this manuscript. This work was funded by national research grants CGL2013-41256-P (MARES) and CTM2017-87227-P (SPEAD) from the Spanish government to S.M.V. and by the Gordon and Betty Moore Foundation through grant GBMF2550.06 to R.M.G. All authors contributed to and reviewed the manuscript. All figures under copy-right have been reproduced with permission.

Mollicutes

Introduction

Despite their notorious fastidiousness and difficulty growing in axenic culture, the first member of what became known as the class *Mollicutes* was isolated more than a century ago. In the early days of microbiology as a discipline, Edmond Nocard and Emile Roux set out to cultivate the agent of the devastating cattle disease, contagious bovine pleuropneumonia (CBPP), and eventually isolated the bacterial species now known as *Mycoplasma mycoides* subsp. *mycoides* (Manso-Silvan et al., 2009; Nocard, 1990). It several decades before the first isolate from humans was collected, and even longer for its true nature to be recognized. Originally termed “Eaton’s agent”, the isolate collected from a patient with primary atypical pneumonia (“walking pneumonia”) was thought to be viral because it could pass through small-pore filters and was unresponsive to treatment with penicillin (Brown et al., 2018). These features of what showed by what is now called *Mycoplasma pneumoniae*, are common to all *Mollicutes* and strongly related to their defining features. They are filterable because they are among the smallest free-living bacteria, and they exhibit intrinsic resistance to penicillins because they lack cell walls (May et al., 2014).

Members of the class *Mollicutes* have evolved degenerately. This streamlined nature makes them excellent systems in which to study major principles in biological sciences including those relating to genomics, synthetic biology, disease emergence, evolvability, gliding motility, and moonlighting proteins. The class also includes several agricultural and human pathogens whose associated diseases have major economic and adverse health impacts worldwide. This article will introduce the cellular biology, phylogeny (and taxonomic challenges), associated diseases and their pathogenesis, genetics/genomics, and societal impact of these unique bacteria.

Phylogeny and Cellular Biology

The class *Mollicutes* is the single member of its own phylum, *Tenericutes*, and is thought to have diverged from common ancestors about 605 Myr (million years) (Maniloff, 2002). Their phylogeny is surprising given their phenotypically distinct absence of a cell wall: they are descended from low G+C Gram positive organisms, with their closest living relatives being the *Firmicutes* (Brown et al., 2018). The class has four orders (class i.e., *Mycoplasmatales*, *Entomoplasmatales*, *Acholeplasmatales*, and *Anaeroplasmatales*) based on aerobic vs. anaerobic growth, sterol requirement, and host range, but the *Mollicutes* on the whole can be subdivided into 5 main branches: *spiroplasma*, *pneumoniae*, *hominis*, *anaeroplasmata* and *asteroleplasma* (Weisburg et al., 1989). The genus *Asteroleplasma*, which includes the single species *Asteroleplasma anaerobium*, is somewhat ambiguous and shares marginal relationships with phyla of other *Firmicutes* and may in the future be reassigned from the class *Mollicutes* (Johansson and Pettersson, 2002). The validly named genera in the class are noted in Table 1.

There are some examples of polyphyly within the *Mollicutes* due to the conflict between species named based on phenotypic characters that have been revisited using molecular techniques. The most striking example is the type species of the genus *Mycoplasma* and the first *Mollicutes* species ever described: *M. mycoides* subsp. *mycoides*. It exhibits the defining traits of the genus in that it is pleomorphic, lacks a cell wall, grows aerobically, requires sterols for growth, and parasitizes a vertebrate host (albeit with unusually high pathogenic potential). However, 16S rRNA gene based-taxonomy led to an unexpected finding: the type species of the genus *Mycoplasma* (along with a few of its close relatives) is not really a mycoplasma at all (Balish et al., 2019; Brown et al., 2018). Ribosomal RNA-based methods, multi-locus sequence typing, and genome-based methods all indicate that *M. mycoides* and its close relatives (collectively called the “*mycoides* cluster”) make up a distinct group in the family *Entomoplasmataceae* (order *Entomoplasmatales*), and are most closely related to members of the genus *Spiroplasma* (Brown et al., 2018). It is no simple task to rename these organisms in a way that would resolve this taxonomic discrepancy. Being the first isolate and the type species, *M. mycoides* has taxonomic precedent over all other members of the genus *Mycoplasma*. According to taxonomic rules, the *mycoides* cluster organisms should retain the genus name *Mycoplasma*, and the other members of the genus should all be given new names. This presents an enormous practical challenge due to the nature of several species within and outside of the *mycoides* cluster. *M. mycoides* subsp. *mycoides* itself, along numerous other *Mycoplasma* species, are World Organization for Animal Health (OIE)-listed pathogens. Both international law and domestic regulations govern the shipping, transport, containment procedures, and reporting of detection for these organisms. Human mycoplasmas, while not reportable, require specific diagnostic and treatment strategies. Changing the names of these organisms would cause potentially catastrophic unintended consequences if careful regulations no longer legally apply. Attempts to resolve this taxonomic discrepancy have been made (Gupta et al., 2018a,b), but the committee that advises the International Committee for the Systematics of Prokaryotes has strongly rejected the proposed changes (Balish et al., 2019; May et al., 2013).

Thorough explorations into mollicutes morphology require electron microscopy due to their small size, although numerous protein localization and structural studies have been successfully carried out using immunofluorescent confocal microscopy and

Table 1 Mollicutes taxa

Order	Defining trait	Family ^a	Defining trait	Genus	Defining trait	Type species
<i>Mycoplasmatales</i>	Aerobic	<i>Mycoplasmataceae</i>	Culturable	<i>Mycoplasma</i>	No urea hydrolysis	<i>M. mycoides</i>
	Sterol requirement			<i>Ureaplasma</i>	Urea hydrolysis	<i>U. urealyticum</i>
<i>Entomoplasmatales</i>	Vertebrate host	'Incertae sedis'	Non-culturable	<i>Haemobartonella</i>	Non-culturable	N/A
	Aerobic	<i>Spiroplasmataceae</i>	Helical morphology	<i>Spiroplasma</i>	Helical morphology	<i>S. citri</i>
	Sterol requirement	<i>Entomoplasmataceae</i>	Non-helical morphology	<i>Entomoplasma</i>	No growth with PES ^b	<i>E. ellychniae</i>
	Invertebrate or plant host			<i>Mesoplasma</i>	Growth with PES	<i>M. florum</i>
<i>Acholeplasmatales</i>	Aerobic	<i>Acholeplasmataceae</i>	Culturable	<i>Acholeplasma</i>	Animal, plant hosts	<i>A. laidlawii</i>
	No sterol requirement	'Incertae sedis'	Non-culturable	" <i>Candidatus</i> Phytoplasma"	Plant hosts	N/A
<i>Anaeroplasmatales</i>	animal or plant host					
	Anaerobic	<i>Anaeroplasmataceae</i>	Anaerobic	<i>Anaeroplasma</i>	Sterol requirement	<i>A. abactoclasticum</i>
				<i>Asteroleplasma</i>	No sterol requirement	<i>A. anaerobium</i>

^a'Incertae sedis' indicates that the taxon is "of uncertain placement" due to lack of valid publication. In each case here, this is because the organisms in question cannot be grown in axenic culture.

^bPES = Polyoxyethylene sorbitan.

cryo-electron tomography (May et al., 2014; Milne and Subramaniam, 2009). Because they do not have a cell wall, most mollicutes lack defined, consistent morphology and are referred to as pleomorphic. There are notable exceptions such as all members of the genus *Spiroplasma*, who retain a distinctive elongated, helical form (Brown et al., 2018), and individual or small groups of species in the genus *Mycoplasma*, which can exhibit polar structures (Balish and Krause, 2006). The periodicity of coils varies among and between *Spiroplasma* species, and assuming the helical structure is tied to twitching and rotational motility (Brown et al., 2018). Acquisition of the genes encoding the linear motor driving spiroplasma motility and the tip structure potentially mediating adherence appears to have occurred at the point of divergence from the rest of the *Entomoplasmataciae*, and are present throughout the genus (Liu et al., 2017). Polar structures are also associated with motility in some mycoplasma, who exhibit gliding motility in the direction of their structure. Unlike the genes conferring spiroplasma morphology and motility, mycoplasma polar structures arose as a result of convergent evolutionary events following horizontal transfer of distinct gene families into a small number of species. The proteins composing the attachment organelles of the closely-related species *M. pneumoniae*, *Mycoplasma genitalium*, *Mycoplasma gallisepticum*, *Mycoplasma testudinis*, *Mycoplasma amphoriforme*, *Mycoplasma pirum*, and *Mycoplasma imitans* are distinctly different in structure, sequence and origin from those composing the polar structure of *Mycoplasma mobile* (Balish and Krause, 2006). Additional gene families encode the ultrastructural proteins giving *Mycoplasma insons*, *Mycoplasma sualvi*, *Mycoplasma penetrans*, and *Mycoplasma pulmonis* their distinct morphologies (Balish and Krause, 2006; Kirchhoff et al., 1984).

Degenerate evolution has led to the loss of many bacterial structures and capacities, and these apparent deficits are often compensated for by utilizing host cell components. Mollicutes lack known mechanisms for DNA repair, nucleotide synthesis, amino acid synthesis, and numerous other functions retained by most free-living bacteria (May and Brown, 2015), undoubtedly lending to their obligate parasitism. Lacking a cell wall suggests that *Mollicutes* species must have unique cell membranes equipped to provide osmotic resistance. Species in the genera *Mycoplasma*, *Ureaplasma*, *Spiroplasma*, *Entomoplasma* and *Candidatus* Phytoplasma incorporate host- (or growth medium-) derived sterols into their membranes (May et al., 2014). *Mollicutes* membranes are also unusually rich in sphingomyelin and/or phosphatidylcholine, and can include phosphatidylglycerol, cardiolipin, or glycolipids (Kornspan and Rottem, 2012; Maquelin et al., 2009; Rottem, 1980).

Mollicutes as Pathogens

To date, there has been infection (natural or experimental) by *Mycoplasma* or *Ureaplasma* demonstrated by isolation of pure cultures or molecular detection in over 100 different animal hosts, with humans, and mammalian, reptilian, avian, and piscine species represented (Brown et al., 2018). The volume of study likely represents the overrepresentation of mammals and birds in the known host range rather than a natural predilection for homeotherms, although this possibility cannot be fully excluded. Only 2 isolated, named species in the class *Mollicutes* (*M. mobile* and *Spiroplasma eriocheiris*) have fish or shellfish hosts. However, recent molecular

examinations of several (non-mammalian, non-avian) aquatic animals found sequences of unnamed *Mollicutes* species in high relative abundance to other members of the microbiota (King et al., 2012; May et al., 2014; Svanevik and Lunestad, 2011). Metagenomic studies have also challenged previous understanding of host range as a defining trait of taxa within the class, identifying mycoplasmas (defined by restriction to vertebrate hosts) in invertebrates (Hulcr et al., 2012; May et al., 2014). As the metagenomes of additional species and environments are characterized, our understanding of *Mollicutes* species host ranges will continue to evolve.

Transmission between hosts occurs primarily by direct contact (includes nose-to-nose contact, sexual contact, or milk feeding) (mycoplasmas, ureaplasmas, achleplasmas, anaeroplasmas), fomite transmission (veterinary mycoplasmas, spiroplasmas [via plant surfaces]), or by insect vector (phytoplasmas, spiroplasmas, entomoplasmas, hemotropic mycoplasmas) (Brown et al., 2018; May et al., 2014). Aerosol transmission of respiratory mycoplasmosis between humans or animals housed in high density (e.g., dormitory settings, military barracks, or livestock and poultry rearing) has also been observed (Atkinson et al., 2008; Feberwee et al., 2006; Tanskanen, 1987). Vertical and perinatal transmission of mycoplasmas, ureaplasmas, and spiroplasmas has been reported (May et al., 2014). The clinical signs of vertically transmitted mycoplasmosis are distinct from those displayed by the infected mother, as congenital infection with *M. hominis* and *Ureaplasma* species can pneumonia, bronchopulmonary dysplasia, meningitis, or encephalitis in (frequently premature) newborns born to mothers with either clinical or subclinical urogenital tract infections (Viscardi, 2010; Waites et al., 2005).

Infection of vertebrate hosts by *Mycoplasma* and *Ureaplasma* species often occurs at mucosal surfaces, and a small number of species can spread to distal tissues from there. Originally thought to exist only as surface pathogens, many species have now been demonstrated to have intracellular phases wherein they can evade adaptive immune responses, antimicrobials, or both. Histopathology generated during mycoplasmosis shows their disease process to be highly inflammatory, and lesions in naturally and experimentally infected animals exhibit hallmarks of chronic inflammatory responses. Mycoplasmosis is infrequently fatal with the notable exceptions of *M. mycoides* subsp. *mycoides*, *M. capricolum* subsp. *capripneumoniae*, and *Mycoplasma alligatoris* (May et al., 2014). The high level of mortality experienced by songbirds afflicted with conjunctivitis due to *M. gallisepticum* stems from an increased susceptibility to predation rather than an enhanced pathogenesis in this particular host (Adelman et al., 2017). The chronic inflammatory nature of most forms of mycoplasmosis makes them diseases of concern for livestock, who often exhibit decreased production and exacerbation of disease with other infectious agents (May et al., 2014) (see also, **Societal Impacts of Mollicutes**) (Table 2).

Human mycoplasmosis can result from infection with *M. pneumoniae*, *M. genitalium*, *Mycoplasma hominis*, *Ureaplasma urealyticum*, *Ureaplasma parvum*, and potentially *M. amphoriforme*. It is currently unclear if *Mycoplasma fermentans* and *M. penetrans* can serve as primary pathogens of humans. The majority of human disease involves the respiratory tract or the urogenital tract, but numerous atypical manifestations particularly of *M. pneumoniae* and *M. hominis* infection affecting the central nervous system, skin, eyes, ears, heart, circulatory system, liver, pancreas, kidneys, and joints (Adelman et al., 2017; Viscardi, 2010) (Table 2). Post-infectious complications following “walking pneumonia” due to *M. pneumoniae* and nongonococcal urethritis due to *M. genitalium* include development of asthmatic exacerbation, adult-onset asthma, pelvic inflammatory disease, spontaneous abortion/adverse pregnancy outcomes, and infertility. An association between *M. genitalium* infection and transmission of human immunodeficiency virus (HIV) is strengthening (May et al., 2014).

The genus *Spiroplasma* contains multiple plant, insect, and crustacean pathogens. Diseases of citrus, corn, honey bees, *Drosophila*, shrimp, and farmed Chinese mitten crabs have high potential for substantial economic losses (Brown et al., 2018) (Table 2). In contrast, reduced survival of *Spiroplasma taiwanense*-infected mosquitos have potential to serve as bioremediation tools. Spiroplasmas are occasionally implicated in cervid or human disease as potential causes of transmissible spongiform encephalopathies (TSEs), but fulfillment of Kock’s postulates have yet to be carried out (Brown et al., 2018).

The genus “*Candidatus Phytoplasma*” is a unique taxon within the *Mollicutes* most closely related to the *Achleplasmataceae*. No member of the genus has yet been reproducibly grown in axenic culture (Brown et al., 2018). Phytoplasmas preferentially infect the phloem sieve elements of plants, and are transmitted via insect vectors. General disease features of phytoplasmosis are variable and species-specific, but can include greening (virescence), phylloidy, stunting, leaf curling, floral sterility, yellowing, purpling, witches’ broom formation, cupping, vein clearing, and failure to thrive. Numerous diseases of important crop species are caused by phytoplasmas (Table 3).

At this time, no members of the genera *Achleplasma*, *Entomoplasma*, *Asteroleplasma*, *Anaeroplasma*, *Mesoplasma* are considered primary pathogens of their respective hosts. Major pathogens in the class *Mollicutes* are listed in Tables 2 and 3, and reviews addressing pathophysiology and virulence factors can be found in the suggested **Further Reading**.

Control of *Mollicutes* infection is challenging. Vaccination is a widely used control strategy for multiple veterinary mycoplasmoses with varying degrees of success. Several vaccines are commercially available for the protection of livestock and poultry against mycoplasmosis. The efficacy of these vaccines remains questionable in many cases, however, emphasizing the continuing issue of mycoplasmosis in veterinary medicine among production animals (May and Brown, 2019). Husbandry practices such as continuous monitoring of flocks and herds and culling of infected populations is an additional practice that is crucial to disease control, particularly for species with no available vaccine such as *S. eriocheiris*. Control of plant diseases due to *Mollicutes* species is reliant solely on husbandry practices such as control of insect vectors and early removal of infected plants (Maejima et al., 2014). Despite numerous experimental vaccines targeting *M. pneumoniae*, vaccination against human mycoplasmosis (respiratory or urogenital) is not currently available. Reduction of contact exposure during both respiratory and sexual transmission are the best measures of prevention.

Table 2 Diseases caused by *Mollicutes* species^a

Species	Host	Disease	Signs
Agricultural (Animal) Pathogens			
<i>M. alkalescens</i>	Cattle	URTD	Nasal discharge, Lameness, Decreased milk production
<i>M. arginini</i>	Cattle	RTI	Infertility
<i>M. bovis genitalium</i>	Cattle	LRTD, URTD, RTI	Nasal discharge, Coughing, Infertility
<i>Mycoplasma leachii</i>	Cattle	Mastitis, arthritis	Lameness, Decreased milk production
<i>M. bovis</i>	Cattle	URTD, LRTD	Coughing, Head tilt, Purulent discharge, Lameness, Decreased milk production
<i>M. bovoculi</i>	Cattle	conjunctivitis	Ocular discharge
<i>M. californicum</i>	Cattle	Mastitis	Decreased milk production
<i>M. canadense</i>	Cattle	Mastitis	Decreased milk production
<i>M. dispar</i>	Cattle	LRTD	Coughing
<i>M. leachii</i>	Cattle	RTI	APO
<i>M. mycoides mycoides</i>	Cattle	CBPP	Coughing, Fever, Torticollis
<i>M. verecundum</i>	Cattle	conjunctivitis	Ocular discharge
<i>M. wenyonii</i>	Cattle	Hemolytic anemia	Malaise, Jaundice
<i>M. gallisepticum</i>	Galliform	CRD, IS, neurological disease, arthritis	Rales, Coughing, Fever, Sinus swelling, Ataxia, Ocular Discharge, Lameness
<i>M. synoviae</i>	Galliform	Arthritis, LRTD, RTI	Rales, Coughing, Sinus swelling, PEQ, Reduced hatchability, Lameness
<i>M. anatis</i>	Duck	URTD	Nasal discharge
<i>M. adleri</i>	Goat	arthritis	Lameness
<i>M. agalactiae</i>	Goat	LRTD, RTI, contagious agalactia	Coughing, ocular discharge, decreased milk production, lameness, APO
<i>M. capricolum</i>	Goat	Contagious agalactia, LRTD, encephalitis	Lameness, decreased milk production, coughing, sudden death
<i>M. capricolum capripneumoniae</i>	Goat	CCPP	Coughing, Fever, Torticollis
<i>M. mycoides capri</i>	Cattle	Contagious agalactia, LRTD	Lameness, decreased milk production, ocular discharge, coughing
<i>M. putrefaciens</i>	Goat	Septicemia, contagious agalactia	Fever, Malaise, Cataracts, Blindness, Lameness, Decreased Milk Production
<i>M. subdolum</i>	Horse	RTI	APO, Infertility
<i>M. haemolamae</i>	Llama	Infectious anemia	Malaise
<i>M. haemosuis</i>	Pig	Hemolytic anemia	Malaise, Jaundice
<i>M. hyopneumoniae</i>	Pig	PEP	Coughing, Malaise, Arrhythmia
<i>M. hyorhinis</i>	Pig	URTD, LRTD	Nasal discharge, Coughing, Arrhythmia, Lameness
<i>M. hyosynoviae</i>	Pig	arthritis	Lameness
<i>M. arginini</i>	Sheep	LRTD, URTD	Nasal discharge, Coughing, Ocular discharge
<i>M. conjunctivae</i>	Sheep, chamois, ibex	conjunctivitis	Cataracts
<i>M. ovipneumoniae</i>	Sheep	URTD, LRTD	Nasal discharge, Coughing
<i>M. ovis</i>	Sheep	Hemolytic anemia	Malaise, Jaundice
<i>M. meleagridis</i>	Turkey	LRTD, RTI	PEQ, Reduced hatchability, Rickets, Skeletal deformity
<i>M. iowae</i>	Turkey	Arthritis, osteitis, RTI	PEQ, Reduced hatchability, Ocular discharge, Lameness, Skeletal deformity
<i>M. pullorum</i>	Turkey	RTI	Reduced hatchability
<i>S. eriocheiris</i>	Ch. Mitten crab	Tremor disease	Tremor; death
<i>S. apis</i>	Honeybees	May Disease	Tremor; paralysis
<i>S. melliferum</i>	Honeybees	Colony loss	Sudden death of bees
Human Pathogens			
<i>M. pneumoniae</i>	Respiratory Tract	PAP; encephalitis; meningitis; conjunctivitis	Post-infections inflammatory complications can occur; additional body sites are rarely implicated
<i>M. genitalium</i>	Urogenital Tract	NGU; PID; cervicitis; orchitis	Infertility, pre-term labor, APOs
<i>M. hominis</i>	Urogenital Tract	BV; cerebral abscess; NGU	Infertility(?); APOs (?)
<i>M. amphoriforme</i>	Respiratory Tract	LRTI	Diagnostic differentiation from <i>M. pneumoniae</i> historically challenging
<i>Ureaplasma</i> spp. (adult)	Urogenital Tract	NGU; chorioamnionitis; endometritis; hyperammonemia	Strain-dependent pathogenicity; APOs; hyperammonemia occurs in immunocompromised patients only
<i>Ureaplasma</i> spp. (neonate)	Respiratory Tract; Central Nervous System	BPD; encephalitis; meningitis	Premature infants born to infected mothers
Wildlife Pathogens			
<i>M. alligatoris</i>	Alligator	LRTD, nephritis, ME, Fulminant inflammatory disease	Rapid death, Lethargy, Rapid death, Lameness

Table 2 (Continued)

Species	Host	Disease	Signs
<i>M. felifaucium</i>	Cheetah, Puma	gastroenteritis	Emesis, Wasting
<i>M. agassizii</i>	Desert tortoise	URTD	Nasal exudates
<i>M. buteonis</i>	Falcon	LRTD, Unclear	Uncoordinated movement, Lameness, Skeletal deformity
<i>M. gallsepticum</i>	Passerines (primarily finches)	conjunctivitis	Ocular Discharge
<i>M. pneumoniae</i>	Hominids (chimpanzee, rhesus monkeys)	PAP, URTD	Coughing, Malaise
<i>M. iguanae</i>	Iguana	Osteitis	Lameness
<i>M. sphenisci</i>	Jackass penguin	URTD	Halitosis, Choanal discharge
<i>M. crocodyli</i>	Nile crocodile	LRTD	Lameness
<i>M. haemodidelphidis</i>	Opposum	Infectious anemia	Malaise
<i>M. orale</i>	Orangutan	URTD	Rales, Nasal discharge
<i>M. columborale</i>	Pigeon	LRTD	Rales, Coughing, Lethargy
<i>M. phocicerebrale</i>	Seal, Human	Eye infection, Seal finger (hu)	Cataracts, Blindness
<i>M. phocirhinis</i>	Seal	URTD	rhinitis
<i>M. zalophi</i>	Sea lion	Necrotizing LRTD	Lameness, Coughing
<i>M. conjunctivae</i>	Sheep, Chamois, Ibex	Conjunctivitis	Ocular discharge, Cataracts
<i>M. kahanei</i>	Squirrel monkey	Hemolytic anemia	Malaise, Jaundice, Arrhythmia
<i>M. sturni</i>	Starling	Conjunctivitis	Ocular discharge
<i>M. mobile</i>	Tench	Red gill disease	Ulceration, labored breathing
<i>M. testudineum</i>	Tortoise	URTD	Nasal discharge
<i>M. corogypsi</i>	Vulture	Abscess	Chronic exudate
<i>M. vulturii</i>	Vulture	LRTD	Rales, Coughing
Companion and Laboratory Animal Pathogens			
<i>M. oxoniensis</i>	Chinese hamster	conjunctivitis	Ocular discharge
<i>M. cricetuli</i>	Chinese hamster	conjunctivitis	Ocular discharge
<i>M. canis</i>	Dog	RTI, UTI, URTD	Frequency, coughing
<i>M. cynos</i>	Dog	pneumonia	Coughing, malaise
<i>M. edwardii</i>	Dog	Septicemia	Fever, Lameness
<i>M. haemocanis</i>	Dog	Infectious anemia	Malaise
<i>M. maculosum</i>	Dog	LRTD, UTI	Coughing, Frequency
<i>M. spumans</i>	Dog	arthritis	Lameness
<i>M. haemominutum</i>	Domestic cat	Infectious anemia	Malaise
<i>M. felis</i>	Cat, Horse	URTD (Fe), LRTD (h)	Nasal discharge, Labored breathing, Ocular discharge
<i>M. gateae</i>	Cat	URTD	Anorexia, lethargy, Ocular discharge, Lameness
<i>M. haemofelis</i>	Cat	Infectious anemia	Malaise
<i>M. equigenitalium</i>	Horse	RTI	APD, Infertility
<i>M. equirhinis</i>	Horse	Inflammatory airway disease	Nasal discharge, Coughing, Rales
<i>M. coccoides</i>	Mouse	Infectious anemia	Malaise
<i>M. haemomuris</i>	Mouse	Infectious anemia	Malaise
<i>M. neurolyticum</i>	Mouse	Rolling disease	Uncoordinated movement
<i>M. pulmonis</i>	Mouse, rat	Murine respiratory mycoplasmosis	Nasal discharge, coughing, anorexia, lameness
<i>M. rapipulmonis</i>	Mouse	Gray lung disease	Coughing
<i>M. arthritidis</i>	Rat	Septicemia, arthritis	Lameness
<i>S. poulsonii</i>	Drosophila spp.	Sex ratio abnormalities	Overabundance of males due to lethality in females

^aAbbreviations: URTD = upper respiratory tract disease; LRTD = lower respiratory tract disease; RTI = reproductive tract infection; CBPP = contagious bovine pleuropneumonia; CCPP = contagious caprine pleuropneumonia; CRD = chronic respiratory disease; IS = infectious sinusitis; PEP = porcine enzootic pneumonia; APO = adverse pregnancy outcomes; PAP = primary atypical pneumonia; NGU = nongonococcal urethritis; PID = pelvic inflammatory disease; BPD = bronchopulmonary dysplasia; ME = meningoencephalitis; RTI = reproductive tract infection; UTI = urinary tract infection.

Diagnosis and treatment of infection by *Mollicutes* species remain distinct challenges. Commercial diagnostic tests have been available for livestock pathogens for several years, but sensitive and specific diagnostics for *M. pneumoniae* and *M. genitalium* have only become available recently. Diagnostic tests for mycoplasmosis of companion animals are not available. Commercial testing for phytomplasmosis and spiroplasmosis is not available. In the absence of commercial diagnostic tests, laboratory culture or molecular testing can be performed. However, specialized expertise is needed to reliably rule these organisms out, and there are a limited number of laboratories in the world with this capacity.

Treatment of infection with *Mollicutes* is inherently complex due to the absence of many antibiotic targets and their potential for facultative intracellularity. Treatment most frequently employs antibiotics inhibiting DNA replication or protein synthesis including

Table 3 *Mollicutes* diseases of food-producing plants

Species	Plant host	Disease
<i>S. citri</i>	Citrus (orange; grapefruit)	Citrus stubborn
<i>S. kunkelii</i>	Corn/maize	Corn stunt
<i>Candidatus P. asteris</i>	Aster family plants	Aster yellows disease; corn stunt; cabbage proliferation disease; apple sessile leaf; strawberry green petal; blueberry stunt; tomato big bud; potato purple top
<i>Candidatus P. americanum</i>	Potato	Potato purple top
<i>Candidatus P. australasia</i>	Papaya	Papaya yellow crinkle disease
<i>Candidatus P. australiense</i>	Grapevine; papaya; strawberry, peanut, apple, alfalfa, sweet potato	Australian grapevine yellows; papaya die-back; strawberry lethal yellows; peanut witches' broom; cocky apple witches' broom; sweet potato little leaf; alfalfa witches' broom
<i>Candidatus P. mali</i>	Apple	Apple proliferation disease
<i>Candidatus P. prunorum</i>	Stone-containing fruits	European stone fruit yellows
<i>Candidatus P. lycopersici</i>	Tomato	Hoja de perejil
<i>Candidatus P. trifolii</i>	Potato	Colombian potato purple top, potato witches' broom
<i>Candidatus P. ziziphi</i>	Cherry, nectarine	Nectarine yellows; cheery lethal yellows
<i>Candidatus P. aurantifolia</i>	Lime	Witches' broom disease of lime
<i>Candidatus P. brasiliense</i>	Alfalfa	Alfalfa witches' broom
<i>Candidatus P. fragariae</i>	Strawberry	Strawberry lethal yellows
<i>Candidatus P. japonicum</i>	Coconut, sugarcane, strawberry	Coconut lethal yellows; sugarcane yellows; strawberry green petal
<i>Candidatus P. pyri</i>	Pear, peach	Peach yellow leafroll; pear decline
<i>Candidatus P. phoenicum</i>	Almond	Almond witches' broom
<i>Candidatus P. oryzae</i>	Rice, sugarcane	Rice yellow dwarf; sugarcane white leaf
<i>Candidatus P. spartii</i>	Sweet potato	Sweet potato little leaf
<i>Candidatus P. solani</i>	Grapevine	Grapevine yellows
<i>Candidatus P. omaniense</i>	Blueberry, peach, sugarcane, grapevine, walnut, cherry	Blueberry proliferation; Canadian peach X; little peach; sugarcane yellows; Virginia grapevine yellows; walnut witches' broom; cherry buckskin disease ("Western X")

tetracyclines, macrolides, fluoroquinolones, aminoglycosides, and certain ketolides. Aminoglycosides, pleuromutilins, and phenicols are frequently used in veterinary medicine, but are not currently used to treat human mycoplasmosis under normal circumstances (Bebear and Kempf, 2005). Mycoplasmal infections can often require long-term antimicrobial therapy, as it is not unusual for disease to recur following the cessation of short-term treatment (Jensen, 2004). Because many *Mollicutes* infections of humans are treated empirically in the absence of readily available, point-of-care diagnostic tests, the need for long-term antibiotic therapy presents a unique challenge in the age of antimicrobial stewardship. Short courses, or even single-dose treatment, of walking pneumonia and nongonococcal urethritis are standard, and they are frequently effective against non-mycoplasma agents (Atkinson et al., 2008). The risk of recurrence of mycoplasmosis due to insufficient therapy, often resulting in intermediate- or resistant strains, must be weighed carefully against the desire to appropriately use antibiotics.

Genetics and Genomics

Mollicutes genomes are among the smallest of free-living organisms. Comparative genomics studies suggest that the small genome size stems from gene loss that occurred early in the divergence of *Mollicutes* from their common ancestor with *Firmicutes*. Ongoing gene loss is still occurring, however, and can be observed by comparing gene sets within each of the phylogenetic branches. Despite an overall trend toward gene loss, the genomes of several mollicutes show extensive evidence of gene gain via horizontal gene transfer (HGT) (Sirand-Pugnet et al., 2007). HGT events have occurred between several species that share common host habitats, and multiple single species show evidence of acquisition of traits from distantly related bacteria (May et al., 2014). HGT in the *Mollicutes* represents an opportunity for high impact discoveries, as known mobile genetic elements that mediate gene exchange are relatively uncommon across the class compared to other bacterial clades. Mobile elements seen in the class include insertion sequence elements, integrative conjugal elements (ICE), bacteriophage, and plasmids; however, bacteriophage and plasmids are largely restricted to spiroplasmas, entomoplasmas, and the *M. mycoides* cluster. Species across the class exhibit extensive evidence for HGT despite the relative paucity of known genetic elements that could mediate the exchanges.

Organisms in the class *Mollicutes* have been the basis for additional pioneering studies in the field of genomics. *M. genitalium* was among the first organisms to have its complete genome sequenced (Fraser et al., 1995) and its genome was the first to be made as a fully artificial chromosome (Gibson et al., 2010). The genome of *M. genitalium* was also the basis for studies on the concept of a

minimal cell (Glass et al., 2006; Koonin, 2000) and experimental attempts to generate a cell with the fewest possible genes while maintaining the capacity for axenic culture have been (Glass et al., 2006; Juhas et al., 2011; May et al., 2014). *Mycoplasma mycoides* subsp. *capri* was the first organism whose complete genome was created artificially and transplanted to result in a living cell, realizing the original vision behind the field of synthetic biology (Gibson et al., 2010; Lartigue et al., 2007).

Societal Impacts

Agricultural Losses

Mycoplasmosis of livestock and poultry and phytoplasmosis of several crop species lead to billions of dollars of economic loss each year. Several *Mollicutes* species cause diseases that are listed by OIE, the International Plant Protection Convention (IPPC), and the Food and Agriculture Organization of the United Nations (FAO) because of the potentially devastating impact on local economies, nutrition, and food availability. While not routinely fatal, the morbidity associated with mycoplasmosis of poultry, swine, cattle, and small ruminants results in decreased production in the forms of lowered feed conversion, downgraded carcasses, loss of egg production, loss of milk production, eggs or milk of inferior (i.e., unable to be sold) quality, and infertility. The most common livestock and poultry diseases include porcine enzootic pneumonia due to *Mycoplasma hyopneumoniae*, chronic respiratory disease/avian mycoplasmosis due to *m. gallisepticum* and/or *Mycoplasma synoviae*, and bovine mastitis/contagious agalactia due to *M. agalactiae*, *M. mycoides* subsp. *capri*, *M. capricolum* subsp. *capricolum*, and *M. putrefascens*. Over and above these diseases, potentially catastrophic economic losses can occur due to outbreaks of CBPP and contagious caprine pleuropneumonia (CCPP). Both diseases have been eradicated from Western Europe, the Americas, and Australia; however, their impact on the livelihood of sub-Saharan Africans in particular is widespread and multi-faceted. Cattle with CBPP are often culled or experience natural mortality. Survivors produce 90% less milk, provide substantially less meat, and are far less able to perform production work (Mariner and Catley, 2003; Tambi et al., 2006; Thiaucourt, 2008). Control of CBPP and/or CCPP during active outbreaks often manifests as quarantine, which is further devastating for pastoralists. Infected herds under quarantine have severely restricted movement, and animals may not be able to access grazing grounds or water sources. Quarantine also often prevents the animals from being brought to markets. Both the health of uninfected animals in the herd and the ability of farmers to access the value of their cattle or goats (Barrett et al., 2004) is impacted by the practice of quarantine. The loss of a food source has a community-level negative impact in addition to the monetary burden on farmers (Thiaucourt, 2008). Both CBPP and CCPP are OIE-listed diseases, and cases of either one in a previously disease-free country can trigger freezing of exportation of animal products to non-endemic countries.

Several grain crops, fruit trees/bushes, nut trees, vegetables, and ornamental plants are affected by phytoplasma or spiroplasma diseases. The distribution of phytoplasmoses is worldwide, and affected crops include rice, corn, wheat, barley, onions, sweet potatoes, celery, carrots, lettuce, citrus, cherries, strawberries, coconut, vineyard grapes, peaches, walnuts, pecans, almonds, alfalfa, potatoes, papaya, apples, tomatoes, and many others. Phytoplasmosis is often slow to develop, making its detection in time to prevent spread challenging. Economic losses are substantial for producers of food crops and ornamental plants, and can border on catastrophic for viticulturalists should their grapevines exhibit bois noir disease ("grapevine yellows", "grapevine flavescence dorée"). Significant diseases of deciduous and coniferous trees are caused by phytoplasmas, and diseases of honeybees are associated with two spiroplasmas. These diseases, while not directly affecting food supplies, have the potential to exert profound ecological devastation with wide-ranging implications.

Complications and Consequences of Urogenital Mycoplasmosis in Humans

The association of urogenital mycoplasmosis with pelvic inflammatory disease, infertility, spontaneous abortion, and preterm labor is significant. *M. genitalium* infection is strongly associated with pelvic inflammatory disease, spontaneous abortion, and infertility in addition to its primary clinical presentation of nongonococcal urethritis (May et al., 2014). Clinical findings associated with *Ureaplasma* spp. and *M. hominis* are highly variable, likely in concert with strain- or patient-specific factors, but both organisms have been associated with spontaneous abortion or preterm labor (Viscardi, 2010). While spontaneous abortion and preterm labor occur during active infection, pelvic inflammatory disease and infertility persist even if infection is resolved. Tubal factor infertility due to *M. genitalium* is often permanent for women. Ureaplasmosis of pregnant woman leading to preterm labor/premature rupture of membranes is a significant risk factor neonatal respiratory tract or central nervous system infections. Chronic lung conditions often persist in surviving infants following the resolution of infection (May et al., 2014; Thiaucourt, 2008). Impaired fertility, chronic pain, and lifelong complications from premature delivery can have significant impacts on economic livelihood and quality of life.

Several reports indicate that there is a synergistic relationship between infection with certain *Mycoplasma* species and human immunodeficiency virus (HIV). *M. genitalium* infection leads to increased vaginal shedding of HIV in patients not on antiretroviral medications, indicating that this organism can have enormous public health consequences that extend beyond acute mycoplasmosis (Manhart et al., 2008; Perez et al., 1998). It has also been hypothesized that *M. penetrans* acts as a co-factor in the progression from subclinical HIV infection to the development of acquired immune deficiency syndrome (AIDS). *M. penetrans* strongly stimulates T cell proliferation and thus HIV replication (Blanchard, 1997; Sasaki et al., 1995). Initial *in vitro* results further supported this by demonstrating that the cytotoxic effect of HIV is enhanced in the presence of contaminating mycoplasmas (Lo et al., 1991; Montagnier and Blanchard, 1993). Antibodies against *M. penetrans* are far more common in AIDS patients relative to HIV positive,

non-AIDS patients or HIV negative patients (Grau et al., 1998; Wang et al., 1992). In light of this somewhat tantalizing evidence, prospective studies are necessary to further evaluate the potential of *M. penetrans* as a driver of AIDS progression.

Conclusions

Members of the class *Mollicutes* are biologically unique organisms that serve as outstanding conceptual models for many biological principles. The class contains many important pathogens and organisms that have been developed as outstanding tools with which to explore fundamental biological questions. Biological, clinical, and applied research on *Mollicutes* is fostered by the International Organization for Mycoplasma, and is presented at the organization's biennial congress.

Introduction

Humans are in direct contact with many pathogens mainly via water used for drinking, washing, and cooking. One of the sources of pathogens in the environment is wastewater discharged with or without treatment or recycled for many purposes (Fig. 1). Therefore there is a need to control and monitor this entrance route of pathogens. The evaluation of pathogen removal by any treatment system and of the final pathogen content in the effluent is of importance in assessing the health risks of treated sewage. Sewage discharge is considered as a worldwide risk factor for the introduction of human pathogens in surface waters. Untreated or insufficiently treated wastewater has often been reported as the primary source of contamination in groundwater. Therefore, removal of pathogenic organisms is one of the important objectives of municipal wastewater treatment.

Occurrence of Pathogens in Municipal Wastewater

Several pathogens and parasites are commonly found in municipal wastewater and in treated wastewater. Some of the important pathogens found in municipal wastewater are listed in Table 1. Important bacterial pathogens found in wastewater are generally associated with diarrhoea, and include *Salmonella*, *Shigella*, *Vibrio cholerae*, *Campylobacter* and *Escherichia coli*. While diseases caused by *Salmonella* and *Vibrio cholerae* are prevalent in developing countries, *Campylobacter*-associated gastroenteritis is more common in developed countries including the United States.

Many viruses exist within wastewater, especially enteric viruses, which originate from the human gastrointestinal tract. More than 160 enteric viruses have been identified to be pathogenic to humans at low infectious doses. It is presumed that many outbreaks of waterborne diseases may be attributed to enteric viruses. Among the important enteric viruses, rotavirus is a common cause of

Table 1 Most frequently detected pathogens in municipal wastewater

Bacteria	Protozoa
Salmonella	<i>Cryptosporidium parvum</i>
Shigella	<i>Giardia lamblia</i>
<i>Campylobacter jejuni</i>	<i>Entamoeba histolytica</i>
<i>Vibrio cholera</i>	
<i>Escherichia coli</i>	
<i>Yersinia enterocolitica</i>	
<i>Legionella</i> spp.	
Viruses	Helminths
Poliovirus	<i>Ascaris lumbricoides</i>
Hepatitis A virus	<i>Trichuris trichiura</i>
Rotoviruses	<i>Necator americanus</i>
Echoviruses	
Adenoviruses	

infection among children under the age of two in developing countries. Waterborne hepatitis by hepatitis A and E viruses is also common in these regions.

Among the protozoan pathogens, *Cryptosporidium parvum*, *Giardia lamblia*, and human virulent microsporidia are human anthroponozoonotic enteropathogens that inflict considerable morbidity on healthy people, particularly children, and can cause mortality (in immunosuppressed individuals). *Cryptosporidium* and *Giardia* are very frequently transmitted via water. The transmissible stages, that is, oocysts, cysts, and spores, are environmentally robust and therefore ubiquitous in aquatic habitats. These enteropathogens are categorized as category B biodefense agents by the National Institute of Health, and microsporidian spores are on the Contaminant Candidate List of the US Environmental Protection Agency because spore identification, removal, and inactivation in drinking water is technologically challenging. Only low numbers of *Giardia* cysts and *Cryptosporidium* oocysts need to be ingested to cause infection. *Entamoeba histolytica* is a major cause of morbidity and mortality in developing countries, while waterborne transmission is rare in developed regions. Reported concentrations of pathogens found in feces are presented in Table 2. The concentrations of enteric pathogens in municipal wastewater are much higher in developing regions compared to developed countries due to higher rates of infection in the developing world.

Table 2 Concentration of pathogens in feces

Organism	Concentration per g of feces
<i>Salmonella</i> spp.	10^4 – 10^{10}
<i>Shigella</i> spp.	10^5 – 10^9
<i>Vibrio cholerae</i>	10^7
<i>Campylobacter</i>	10^7
Rotavirus	10^{10}
Adenovirus	10^{11}
Hepatitis A virus	10^6
<i>Giardia lamblia</i>	10^6
<i>Cryptosporidium</i>	10^6 – 10^7
<i>Ascaris lumbricoides</i>	10^4

Indicator Organisms

Since direct monitoring of pathogenic microorganisms in water and wastewater requires costly and time-consuming procedures and skilled manpower, indicator organisms have been used to assess the presence of fecal contamination and efficiency of wastewater treatment processes. Coliform group was first accepted as an indicator of fecal pollution drinking water in early twentieth century. Since then, various microorganisms have been used for indicating the presence of fecal contamination. Since it is now recognized that there is no direct correlation between bacterial indicators and pathogenic organisms, use of indicators is now defined by their intended purposes such as fecal contamination indicators and process efficiency indicators. Generally used and proposed indicators are the following: (i) total coliforms (ii) fecal coliforms (thermotolerant coliforms) (iii) *Escherichia coli* (iv) fecal streptococci (v) *Clostridium perfringens* (vi) bacteriophages. Bacteriophages are viruses that infect bacteria. Bacteriophage that infect *Escherichia coli* are commonly referred to as coliphages. Bacteriophages, which are commonly found in the feces of humans and warm-blooded animals, are considered by some researchers to be good indicators because they have fundamental properties and features, such as structure, composition, size, and replication mode, similar to enteric viruses. Coliphages have been detected wherever fecal contamination occurs. Many studies have proposed the use of coliphage as indicators of enteric viruses.

Table 3 presents the reported levels indicator organisms and pathogens in raw municipal wastewater. The occurrence of all these species can vary from one country to another, or even from one city to another, or during daily hours due to wastewater-generating characteristics. For example, the occurrence of parasite ova, cysts, and fecal coliforms (FC) in urban wastewater and their removal was determined after sewage treatment in gravel bed hydroponic (GBH) constructed wetlands (CWs) receiving conventionally treated wastewater at Abu Attwa, Ismailia, Egypt. Samples of raw wastewater and GBH influents and effluents were examined for eggs of intestinal helminths for over 2 months in 1995. All raw wastewater samples were found to be positive for *Ascaris lumbricoides* but eggs of *Hymenolepis* spp., *Trichuris* spp., *Ancylostoma duodenale*, and *Toxocara* spp. were also detected in raw and conventionally treated wastewaters. In Ismailia, the concentration of eggs of human intestinal helminths in raw wastewater ranged from 6 to 42/l. In the influent to the GBH beds, the concentration of helminth eggs was reduced and ranged from 0 to 11/l; eggs of *Ascaris* were found in 28% of the samples. No helminth eggs were recovered from GBH-treated effluents. Cysts of protozoa and FC bacteria were also removed by GBH beds to some degree. Raw wastewater contained cysts of the protozoa *Entamoeba coli*, *Entamoeba histolytica*, and *Giardia* spp. Although the density and diversity of species was reduced after treatment in the GBH beds, some amoebic cysts were found in the effluents. FC removal averaged 2–3 logs during sewage treatment in GBH beds but effluents did not satisfy WHO guidelines for unrestricted irrigation. This survey indicates that GBH beds have the capacity to remove pathogens from wastewaters. Improvement in wastewater quality after GBH treatment satisfied WHO microbiological quality guidelines for restricted irrigation. With a retention time of 6 h, GBH CWs have practical applications for wastewater treatment for safe reuse in Egypt.

Table 3 Reported levels of pathogens and indicators in raw sewage

Organism	Concentration per 100 ml
Total coliforms	10^7 – 10^9
Fecal coliforms	10^6 – 10^7
Fecal streptococci	10^5 – 10^6
<i>Clostridium perfringens</i>	10^4
Coliphages	10^2 – 10^3
<i>Salmonella</i>	10^2 – 10^4
<i>Giardia</i> cysts	10^1 – 10^3
Enteric viruses	10^1 – 10^5
<i>Cryptosporidium</i> oocysts	10^1 – 10^3

Removal of Microorganisms by Wastewater Treatment Processes

One of the important objectives of municipal wastewater treatment is the removal of pathogenic microorganisms. Therefore, treatment technologies for wastewater have been continuously improving due to stringent limits set including microbial control and limits set for treated wastewater reuse practices. Generally municipal wastewater treatment comprises three phases namely, primary, secondary and tertiary treatment. Fig. 2 shows the common approach for treatment of municipal wastewater with tertiary treatment processes, and the integration of advanced oxidation processes (AOPs). In general, the common treatment technologies are able to remove pathogens at different levels as shown in Tables 4, 5.

In primary treatment, large solid particles are physically separated from the wastewater in a settling tank. The settled solids are referred to as primary sludge. Primary sedimentation is effective for removal of larger pathogens such as helminthes. In addition, solid-associated pathogens are also removed to some extent. Total coliform removals in the range of 25–70% have been reported. Secondary treatment generally consists of biological processes such as activated sludge process, trickling filter, lagoon (pond) or anaerobic process such as upflow anaerobic sludge blanket reactor. Tertiary treatment is used to further reduce pathogens and other contaminants so as to protect water bodies or to reuse the treated wastewater. Physico-chemical processes such as coagulation, adsorption, filtration and disinfection are generally used for this.

Factors Affecting Microbial Removal in Municipal Wastewater Treatment Systems

A number of factors influence the microbial removal during wastewater treatment. Microbial aggregation and solids association increase settleability while it offers protection from disinfection. Higher temperature generally results in rapid inactivation of microbes as a result of denaturation by thermal effect, by increased enzymatic activity in biological processes or by faster reaction rates in chemical processes. However, elevated temperature may result in increased growth for some pathogens such as *Vibrio* spp. and *Legionella* spp. Biological activity can also reduce pathogens by predation mechanisms such as grazing, or by increased enzymatic activity by bacteria. Biofilm and floc formation also reduce pathogens by increased adsorption and accumulation. Sunlight influences the pathogen removal especially in pond systems.

Fig. 2 Municipal wastewater treatment and disinfection technologies.

Table 4 Comparison of removal efficiency of some parameters for common treatment systems

Treatment systems	Removal efficiency (%)			
	BOD	N	P	Coliforms
Prechlorination	15–30			90–95
Primary settling	25–50			25–70
Coagulation and flocculation	50–85			40–80
Stabilization ponds	75–90	30–50	20–60	60–99
Activated sludge	85–95	30–40	30–45	60–90
Low rate trickling filters	85–90	30–40	30–45	60–90
Anaerobic treatment	60–80	10–25	10–20	60–90
Aerated lagoons	90–95			95–98
Postchlorination				98–99

Table 5 Removal of pathogens in stabilization ponds and constructed wetlands

Secondary Treatment Systems

Activated Sludge Process and Membrane Bioreactor

Pathogen removal by conventional activated sludge (CAS), which is widely used to treat municipal wastewater, is highly variable depending on the type of organisms and detention time. Up to 2 log reduction of organisms has been reported. Since activated sludge effluents have been shown to contain high levels of pathogens that may pose an unacceptable hazard to human health, particularly when the treated effluent is reused. In recent years, membrane bioreactors (MBR) technology has emerged as an alternative to conventional activated sludge process for municipal wastewater treatment. In MBR a permselective membrane is used in combination with a biological process. In MBR systems, secondary sedimentation is not needed for separation of solids since removal of solids is achieved by the membrane. The small pore size of the membrane also results in the physical removal of a wide variety of microorganisms.

In a study to compare the performance of MBR and CAS with tertiary treatment in removing microbial pathogens, TC and FC and somatic and F-specific coliphage were used as indicators of pathogenic bacteria and viruses. Each MBR pilot had a hydraulic retention time (HRT) of ~6 h with a solid retention time (SRT) of 18 days and mixed liquor suspended solids (MLSS) of ~10 g/L. Average concentration of TC and FC was 2.5×10^7 CFU/100 mL and 9.6×10^6 CFU/100 mL, respectively, while average concentration of somatic and F-specific coliphage was 2.9×10^5 PFU/100 mL and 1.79×10^5 PFU/100 mL, respectively. Up to 5.7 log removal of coliforms and 5.5 log removal of coliphage were observed in the conventional treatment process with advanced tertiary treatment (RBC, sand filtration, and chlorination). Complete removal of FC and up to 5.8 log removal of coliphage was observed in the MBR system. It was shown that the MBR system was capable of high removal of coliphage despite the variation in feed coliphage concentrations. Compared with the CAS process followed by tertiary treatment, the MBR pilot plants achieved better FC removal by more than 1 log unit. The MBR permeate was shown to be suitable for unrestricted reuse while the advanced tertiary system did not meet the pathogen removal limits. The results of this study indicate that the MBR process can achieve better microbial removal in fewer steps than a CAS process with advanced tertiary treatment.

The removal of human enterovirus (EV) and norovirus genogroup II (NoV GGII) was studied in a full-scale MBR wastewater treatment plant and compared with the removal of human adenovirus (HAdV) (Simmons et al., 2011). Samples were collected from four separate locations throughout the treatment process; influent, primary settling effluent, membrane influent and membrane effluent. EV was detected in all 32 samples with an average concentration of 1.1×10^7 and 7.8×10^1 viruses/L for the

membrane influent and membrane effluent, respectively. NoV GGII was detected in 20 of 32 samples (63%) with an average membrane influent and membrane effluent concentration of 2.8×10^5 and 1.2×10^1 viruses/L, respectively. HAdV was detected in all 32 samples with an average membrane influent concentration of 5.2×10^8 and 2.7×10^3 viruses/L in the membrane effluent. Results indicated that the full-scale MBR treatment was able to reduce the viral loads by approximately 5.1 and 3.9 and 5.5 log units for EV, NoV GGII and HAdV, respectively. This full-scale MBR system outperformed the removal observed in previous pilot and bench scale studies by 1–2 log units.

Purnell et al. (2015) assessed the removal efficacy of viruses in a full-scale membrane bioreactor (MBR) wastewater reuse system, using a range of indigenous and 'spiked' bacteriophages. Mean levels of fecal coliforms were reduced to 0.3 CFU/100 mL in the MBR product and were undetected in samples taken after the chlorination stage. The microbial removal values recorded were greater than those commonly reported for conventional activated sludge treatment. A large reduction (5.3 log) in somatic coliphages was also observed following MBR treatment. However, F-specific and human-specific (GB124) phages were less abundant at all stages, and demonstrated log reductions post-MBR of 3.5 and 3.8, respectively. Spiked phages (MS2 and B-14) displayed post-MBR log reductions of 2.25 and 2.30, respectively. The removal of these suspended phages, which are smaller than the membrane pore size (0.04 μm), also highlights the possible role of the membrane biofilm as an effective additional barrier to virus transmission. The study suggested that phage removal in MBR systems is highly variable and may be closely related on both the size and morphology of the viruses, and to whether or not they are attached to solids. It also showed that monitoring several phage groups would be required to assess the ability of MBR to remove enteric viruses.

Stabilization Ponds

Waste stabilization ponds (SP) have been extensively used for treatment of domestic wastewater all over the world, especially in small cities and towns of developing countries as a low-cost method of pathogen removal for wastewater reuse. The low cost and simplicity of their construction, operation, and maintenance has made them one of the most important wastewater treatment technologies, in particular when the effluent is land-applied. Sunlight is an important factor for the removal of microbes in these systems. Natural die-off, predation, sedimentation, and environmental parameters such as pH, dissolved oxygen and temperature also influence the pathogen removal.

In Spain, a waste stabilization pond (WSP) system consists of two anaerobic ponds, a facultative pond and a maturation pond with a total retention time of 6 days was evaluated for their efficiency in the removal of fecal indicator bacteria (total coliforms, *E. coli* and fecal streptococci), coliphages, helminth eggs and protozoan cysts (*Cryptosporidium* and *Giardia*) (Reinoso et al., 2011). The results showed that the pond system significantly reduced the concentration of pathogenic and indicator microorganisms from wastewater producing a final effluent suitable for agricultural irrigation. The overall removal of the system ranged from 1.4 log units for coliphages in the cold period to 5.0 log units for *E. coli* in the hot period. *Cryptosporidium* oocysts were reduced by an average of 96% and *Giardia* cysts by 98%. Complete removal of helminth eggs was also observed. The surface removal rates reflected that anaerobic ponds were the most effective in removing parasites followed by facultative pond and maturation pond. Sludge samples also revealed that anaerobic ponds were the most effective in parasite removal. However, sludge samples indicated that sedimentation was not the main removal mechanism. Other factors such as sunlight, pH, temperature and dissolved oxygen were comparatively more important in reduction of pathogens in this system (Reinoso et al., 2011).

The removal of TC, FC, and coliphage in waste SP functioning as a pilot system in the tropical climate of Maracaibo, Venezuela, was investigated. Sampling points included raw sewage and each pond effluent. Turbidity, pH, and temperature were recorded. The results for raw sewage showed average levels of 4.1×10^6 TC and 2.8×10^6 FC/100 mL. Temperature, pH, and turbidity ranges between 26 and 31°C, 6.2 and 9.5, and 15 and 98 NTU, respectively. Removal rate of microorganisms in the three systems ranged between 93% and 98%. Despite the high removal efficiency of microorganisms, the final effluents showed average counts of 5.4×10^4 – 1.4×10^5 TC and 5.2×10^4 – 1.3×10^5 FC/100 mL. This study shows that the microbiological quality of the final effluents did not achieve the WHO water quality requirement for FC (10^3 /100 mL); therefore, they cannot be used for irrigation. Additional treatments, such as slow sand filtration, are needed in order to improve the quality of the water.

Verbyla and Mihelcic (2015) reviewed virus removal reported in the literature from 71 different wastewater treatment pond systems. Only a weak to moderate correlation of virus removal with theoretical hydraulic retention time was observed. On average, one log reduction of viruses was achieved for every 14.5–20.9 days of retention, but the 95th percentile value of the data analyzed was 54 days. Among the different mechanisms, sedimentation may not be a significant virus removal mechanism in some wastewater ponds. Direct and indirect sunlight-mediated mechanisms are not only dependent on pond water chemistry and optics, but also on the characteristics of the virus.

Anaerobic Systems

Upflow Anaerobic Sludge Blanket (UASB) reactors are the most widely used anaerobic technology for domestic wastewater treatment in tropical and semi-tropical conditions. Pathogen removals have been reported to be low during anaerobic treatment. Thus, UASB reactor effluent has to undergo post treatment in order to meet the discharge standards.

A combination of UASB reactor and downflow hanging sponge (DHS) anaerobic treatment reactors was compared with activated sludge process for removal of TC and FC. Raw sewage for both systems had coliforms in the order of 10^7 – 10^8 MPN/100 mL. There was only single order removal of coliforms in UASB reactor. However, they were removed by 3–4 orders after the

treatment by DHS. TC and FC removals were 4.0 and 3.7 log units, respectively, by the whole system. But a slight drop in coliform removal was observed during the winter season. Nevertheless, it was observed that UASB+DHS system outperformed ASP in pathogen removal as coliform count in the final ASP effluent was higher. In the final ASP effluent, the removal efficiencies were 3.9 and 3.4 log units for TC and FC, respectively. The higher amount of retained sludge in UASB+DHS system and longer SRT could be the reason for the better performance of the system compared to that of ASP.

The capacity of anaerobic processes for pathogens reduction was studied in a laboratory-scale UASB reactor treating domestic wastewater at low temperatures in Peru (Yaya-Beas et al., 2016). The average total helminth egg (HE) content in the influent wastewater varied between 166 and 256 egg/L and the most common specie was *Ascaris lumbricoides*. Results showed that the HE removal varied between 89% and 95% when the upflow velocity was varied in the range of 0.12–0.41 m/h, with no significant change within the range of upflow velocities studied. Fecal coliform and *Escherichia coli* removals varied in the range of 0.9–2.1 and 0.8–1.6 log respectively. The UASB effluent with a HE content varying between 5 and 35 egg/L did not meet the WHO standards for reuse and a post-treatment unit would be required to polish the effluent.

Constructed Wetlands

Constructed wetlands (CW) are well known as highly efficient systems for treating wastewater from different sources. This treatment system is cost-effective for reuse in desert areas. CWs, of either vertical or horizontal (i.e., free surface or subsurface) flow, are increasingly being used worldwide for secondary or tertiary treatment of municipal sewage. In many developing and developed countries, these reed bed systems discharge to drinking water or waters used for recreational purposes. Reed bed discharges can contribute to microbial buildup in reclaimed water, but these pathogens may not necessarily originate from the wastewater received by these wetlands. While CW systems facilitate nutrient removal, they may not provide substantial protozoan pathogen remediation, despite reported removal efficiencies. The bacterial removal in constructed wetlands can be influenced by a number of factors such as solar radiation, natural cell die-off, sedimentation, filtration and adsorption. Furthermore, predation by nematodes, protozoa, and bacteriophages, and competition for limiting resources may also inactivate bacteria. Virus attenuation is controlled mainly by adsorption and inactivation.

Table 5 gives a background survey of CWs and stabilization ponds for pathogens removal. The role of HRT and granular medium in FC and somatic coliphage (SC) removal in tertiary reed beds was investigated in a pilot plant with four parallel reed beds (horizontal subsurface flow CWs), each one containing a different type of granular medium (near Barcelona). Secondary effluent from the wastewater treatment plant was used as the influent of the pilot system. The microbial inactivation ranged between 0.1 and 2.7 log units for FC and from 0.5 to 1.7 log units for SC in beds with coarser granular material (5–25 mm), while it ranged between 0.7 and 3.4 log units for FC and from 0.9 to 2.6 log units for SC in the bed with finer material (2–13 mm). The microbial inactivation rises as the HRT increases until it reached a saturation value (in general at an HRT of 3 days). The value of the microbial inactivation at the saturation level depended on the granular medium contained in the bed. The specific surface area necessary to reach 2–3 log units of FC and SC was ~ 3 m²/people equivalent.

A continuous flow, free water surface (FWS) pilot wetland using the duckweed plant *Lemna gibba* L. was constructed at Israel, and operated on domestic primary effluents. Water quality and system efficiency were observed during the experiment for reuse purposes. Results indicated that hydraulic residence time averaged 4.267 ± 0.61 days, average influent flow rate was 0.2347 ± 0.027 m³/day, and hydraulic load 0.227 ± 0.03 m/day. Hydraulic efficiency in the system was high and allowed good settling conditions. Suspended solids and organic matter removals were the highest and effluent concentrations were 13.1 ± 79.7 and 40.37 ± 11.9 mg/L for total suspended solids and total BOD, respectively. Nitrogen removal was lower (10–20%) but increased slightly with higher nitrogen loads. Therefore, nitrogen content in the plants was high ($4.3 \pm 0.5\%$ /kg dry plant). Phosphorus removal was negligible. High removal for FC (95%) and effluent turbidity (>50%) were also observed.

Abreu-Acosta and Vera (2011) evaluated the removal efficiencies of fecal bacteria and enteric pathogens in two wastewater natural reclamation systems. These systems were constituted of a combination of anaerobic treatment, small sub-surface flow constructed wetland refilled of volcanic ashes and a final pond as water reservoir. Fecal coliforms, enterococci, *Escherichia coli*, somatic coliphages, *Salmonella* sp., *Campylobacter* sp., *Cryptosporidium* sp., *Giardia* sp. and helminth eggs were analyzed in constructed wetlands inlet and outlet and storage pond effluent. Low numbers of protozoan positive samples (4.54% and 19.05% for *Giardia* sp.) and an absence of helminth eggs were found. Both systems demonstrated efficient reduction of fecal contamination indicators in the wastewaters (removal rates values of 2 log). The natural systems for wastewater treatment used to be efficient in *Salmonella* abatement, this fact was confirmed in the reported systems, since enterobacteriaceae were found in only one of the effluents. *Campylobacter* species associated with the access of animals to storage ponds were detected in the reclaimed water. The presence of *Salmonella* and *Campylobacter* in the effluents of the evaluated systems implies a potential health risk, although the bacteria presence is minimal when EC are lower than 200 cfu/100 mL.

Tertiary Treatment Systems

Sand Filtration

In recent years, slow sand filtration (SSF) has gained increasing attention as a promising technology for treatment of secondary effluent with the purpose of reuse. Seeger et al. (2016) investigated the use of SSF for removal of pathogen indicators from

secondary effluent of constructed wetlands. With a view to improve SSF performance by an enhanced use of the biologically active *Schmutzdecke* layers, they compared the pathogen indicator removal efficiency of four different SSF designs: standard, recirculating, a static series of two SSFs, and a rotating cascade. All filter configurations gave substantial removal for *E. coli* (≤ 4.7 log), enterococci (≤ 2.4 log), *C. perfringens* spores (≤ 2.1 log), coliphages (≤ 2.8 log) and heterotrophic plate count (HPC) (≤ 1.5 log) with the tested operational conditions. Results showed that only rotating and static cascade systems complied with European irrigation water standards for both *E. coli* and enterococci at hydraulic loading rate = 5 cm/h achieving mean log removal of 2.7–4.7 and 2.1–2.4, respectively. The standard filter showed considerable improvement of removal efficiency for *E. coli* and enterococci during an operation period of up to 1 ½ years. *C. perfringens* spore removal performance was good for all SSFs. Somatic coliphages were reduced to concentrations close to the detection limit, while F-specific RNA coliphage removal was ~ 1.1 log. Removal of heterotrophic bacteria was generally low (0.5–1.5 log) (Seeger et al., 2016).

The performance of rapid sand filtration (SF) was evaluated in three tertiary wastewater treatment plants in the State of Kuwait. These plants are located at Ardiya, Rikka, and Jahra, and receive municipal wastewater flows of 220,000, 95,000, and 42,000 m³/day, respectively. The Ardiya plant uses a two-stage activated sludge process for the secondary treatment of wastewater, whereas both the Rikka and Jahra plants use the extended aeration process. The study was conducted over a period of 1 year, and the efficiency of the tertiary SFs was determined based on reductions in suspended solids (TSS), volatile suspended solids (VSS), BOD, and COD. Analysis of these records showed that the secondary treated effluent quality was highly variable. Seasonal variations were observed due to nitrification and denitrification that enhance the production of nitrogen gas and carry sludge solids in the effluent during summer, causing more frequent backwashing of the filters. The results obtained indicated significant improvements, at 95% and 99% significance levels, in solids (TSS, VSS) and organics (BOD, COD) removal by SF. They also showed that, in addition to improving effluent quality, tertiary filtration played an important role in the stability of effluent quality so as to dampen variations in the quality of secondary-treated effluent. The tertiary effluent consistently satisfied the water quality requirements for irrigation. TC were determined as 2 in Ardiya and 0 and 0 MPN/100 mL in Rikka and Jahra tertiary treated effluents, respectively, which met the guidelines for landscape irrigation (2.2 MPN/100 mL) in Kuwait. Based on current cost figures from wastewater treatment plants in Kuwait, the cost of producing treated effluent using filtration and chlorination for tertiary treatment was about US\$0.50/m³ (\$0.20 wastewater collection plus \$0.30 treatment for reuse). This represented about one-third of the cost of producing 1 m³ of desalinated water using the MSF process as an alternative source for irrigation water in Kuwait.

The occurrence and removal of *Salmonellae* and fecal indicators in four conventional municipal wastewater treatment plants (MWWTP) was investigated. In addition, the efficiency of a semitechnical-scale biological nutrient removal process and three pilot-scale tertiary filtration units in microbial removal were tested. All influent samples collected from MWWTPs contained *Salmonella* from 93 to 11,000 MPN/100 mL and indicator bacteria from about 10⁷ to 10⁸ CFU/100 mL. The reductions in *Salmonella* numbers achieved in full-scale biological–chemical wastewater treatment and semitechnical-scale biological nutrient removal processes were usually between 94% and virtually 100% (99.9%) and indicator bacteria reductions between 2 and 3 log units. Microbial numbers in MWWTP effluents could be modeled as a function of effluent residual organic matter, suspended solids, and total phosphorus concentrations. Pilot-scale tertiary treatment by rapid sand contact filter, chemical contact filter, and biological–chemical contact filter reduced *Salmonella* numbers below the detection limit and FC on average by 99%, 39%, and 71%, respectively. A total of 32 *Salmonella* serovars were identified among 197 *Salmonella* isolates from municipal wastewaters. These results, especially antibiotic-resistant *Salmonella* strains, indicated that conventional municipal wastewater treatment without efficient tertiary treatment, like filtration or disinfection, may constitute a risk for public health.

Membrane Processes

Two polyvinylidene fluoride microfiltration membranes with a nominal pore size of 0.22 µm were challenged with mixed microbial cultures present in Milli-QTM water and in secondary effluent, and with a Gram-negative model bacterium, SW8, to investigate bacterial passage. Total bacterial counts measured microscopically using the DNA Fluorochrome DAPI revealed that the small bacteria in Milli-QTM water passed MF membranes totally. The model bacterium, SW8, and bacteria from secondary effluent were mostly retained with a log removal value (LRV) of 4 and 3.5, respectively. Transmembrane pressure did not influence the levels of bacterial passage significantly. Pore size effects were investigated using track-etched membranes with nominal pore sizes of 0.2, 0.1, and 0.05 µm. The LRV of 0.2 µm membranes for SW8 and secondary effluent cells was 3 and 1.5, respectively (total counts). Both membranes with pore sizes smaller than 0.2 µm acted similarly; they still transmitted secondary effluent cells with LRV 2 log higher than 0.2 µm membranes, but for SW8 only 50% higher. In contrast to total count results, removal of bacteria was 100% with all membranes when assessed by cultureable counts, that is, the number of bacterial colonies recovered on R2A agar plates. Transmitted bacteria failed to grow on standard basal microbiology media most probably because they were injured during passage through the membranes to the extent that recovery in laboratory media did not occur. However, tests with CTC, an indicator of cell viability, indicated that approximately half of the cells of SW8 that passed the membranes had what appeared to be functional electron transfer chains in their membranes. All membranes had a pore size distribution that included pores larger than the nominal value. Field emission scanning electron microscopy provided evidence for entrapment of bacteria within the membrane matrix.

An MBR and reverse osmosis (MBR–RO) system was developed to assess potential reuse applications of municipal wastewater. The objective of the study was to examine the water quality throughout the system with a focus on waterborne pathogens,

disinfection by-products (DBPs), and nitrate. High-quality reuse water could be produced from municipal wastewater through the use of an MBR–RO system. The water meets California Title 22 reuse regulations for nonpotable applications and US EPA drinking water limits for trihalomethanes (THM) (80 mg L^{-1}), haloacetic acids (60 mg L^{-1}), chlorite (1.0 mg L^{-1}), TC (not detectable), viruses (not detectable), and nitrate/nitrite (10 mg N L^{-1}).

A field study on municipal wastewater reclamation for the irrigation of two experimental crops of tomato and fennel aimed at the evaluation of the performance of a membrane filtration pilot plant (productivity $0.7 \text{ m}^3 \text{ h}^{-1}$) for tertiary treatment and the comparison between agronomic results (features of soil and crops) after irrigation with reclaimed wastewater versus conventional groundwater. Over long-term operation, the pilot plant performance results were very good in terms of suspended solids and bacterial removal. Referring to the agronomic results, no substantial differences were observed after 2 years, in terms of both microbiological quality of the crops and characteristics of the soil. The results indicate that membrane-filtered municipal effluent is a viable alternative water resource for irrigation. The performance of the MFPP in terms of microorganisms removal was evaluated by measuring the content of coliforms (total and fecal) and *E. coli* in wastewater samples collected before and after membrane filtration. Average removal efficiencies for TC, FC, and *E. coli* resulted in 3.7, 4.2, and 3.7 log, respectively. The average content of TC in membrane-filtered wastewater was below $1000 \text{ CFU}/100 \text{ mL}$. In any case, the residual bacterial content of the membrane permeate did not reflect the claimed feature of this technology that, based on the nominal membrane pore size (0.03 mm), should remove ‘all bacteria’. Interestingly, microbiological analyses on the conventional well water normally and legally used for irrigation showed much higher average concentrations of TC and FC than those measured in the membrane-filtered wastewater. The concentrations of *E. coli* were only measured during period 4 and were found to be comparable to those observed in the permeate ($10 \text{ CFU}/100 \text{ mL}$ on average).

Advanced Oxidation Processes and Disinfection

Photocatalytic and membrane processes are strong candidates for improving conventional water treatment processes. These advanced treatment methods are capable of removing many pollutant chemicals as well as pathogenic microorganisms. The performance of small-scale UV/TiO₂ photocatalytic pilot plant process in treating secondary and tertiary treated effluent from a wastewater treatment plant in Bahrain was investigated. The performance was evaluated in terms of the efficiency of removing a chlorine-resistant parasite, namely, *Strongyloides stercoralis*, in addition to reducing the chemical oxygen demand (COD). The effect of pH and exposure time was considered. The performance of UV/TiO₂ was compared with small pilot-scale UF and RO membrane processes. Treatment of the samples with each of the UV/TiO₂, UF, and RO processes resulted in a complete removal of *S. stercoralis* parasites. Moreover, the COD was reduced by about 50%, 64%, and 86% with each of UV/TiO₂, UF, and RO. The specific power consumption of the UV/TiO₂ process was estimated to be about 4.0 kWh/m^3 for each of UV/TiO₂ and seawater RO and 1.0 and 0.9 kWh/m^3 for each of brackish water RO and cross flow UF, respectively. The UV/TiO₂ process generates no waste stream, whereas the RO and UF processes generate waste streams, which are concentrated in the microorganisms, and suspended organic matter, which result in a disposal problem.

The experimental results of a pilot-scale ($100 \text{ m}^3 \text{ h}^{-1}$) investigation, carried out at the West Bari (Southern Italy) municipal wastewater treatment plant, focused on parasite removal and DBP formation during the UV disinfection of clarified (CL) and clarified-filtered (F) secondary municipal effluents. The investigation demonstrated that parasites like *G. lamblia* cysts and *C. parvum* oocysts were both significantly affected by UV radiation and that potential UV-promoted formation of DBPs (nitro-phenols and N-nitroso-amines) did not occur according to GC/MS and LC/MS analytical evidences. Operational and maintenance costs ranged from ~ 17.5 up to euros $35/1000 \text{ m}^3$ for effluent F and CL, respectively.

Removal of bacteria by ozonation in combination with charcoal or slow sand filtration was compared with that by flocculation filtration in pilot scale at the sewage treatment plant Eriskirch, Baden-Wuerttemberg, Germany (Lüddecke et al., 2015). Influent and effluent of different treatment processes were analyzed in a culture-based approach for its content of *Escherichia coli*, enterococci and staphylococci and their resistance against selected antibiotics over a period of 17 months. Ozonation followed by a filter passage led to an additional reduction of total and antibiotic resistant *E. coli*, enterococci and staphylococci between 0.8 and 1.1 log-units as compared to the respective concentrations in treated sewage by only flocculation filtration. However, ozonisation led to an increased percentage of antibiotic resistant *E. coli* (16%) and staphylococci-isolates (5.5%) and a decrease of the resistance-level of enterococci (25.4%). Overall, advanced wastewater treatment by ozonation plus charcoal or sand filtration after common sewage treatment is an effective tool for further elimination of microorganisms from sewage before discharge in surface waters (Lüddecke et al., 2015).

Conclusions

It is clear that municipal wastewater harbors a variety of pathogenic organisms. A number of technologies are available today to treat wastewater for different intended uses. Treatment technologies for wastewater have been continuously improving due to the stringent limits set, including microbial control, and also due to reuse practices because of the increasing water scarcity in a number of regions of the world. It is necessary to continuously monitor the microbial quality of treated wastewater in order to ensure that the treatment objectives are achieved. Generally a combination of different processes only would ensure complete removal of pathogens from wastewater.

Glossary

Alkaloid Any of various natural bases derived from amino acids that contain one or more heterocyclic nitrogen atoms.

Mycosis (plural: mycoses) A mycosis is a disease produced by pathogenic invasion of a fungus on an animal host.

Mycotoxicosis (plural: mycotoxicoses) A mycotoxicosis is an animal disease produced by exposure to mycotoxins. Eating contaminated foods and feeds is the most common cause of mycotoxicosis; however, some mycotoxins cause disease upon dermal contact or inhalation.

Mycotoxin A low molecular weight natural product, produced by a filamentous fungus that is harmful to animals in low concentration. Curiously, toxic metabolites made by mushrooms and other macroscopic fungi usually are classified separately as 'mushroom poisons'.

Nonribosomal peptide A short peptide that is synthesized by a nonribosomal method, that is, peptide formation occurs in the absence of the usual translational machinery by nonribosomal peptide synthases. They often contain unusual amino acids.

Polyketide Any of a diverse group of natural products synthesized via linear poly- β -ketones, which are themselves formed by repetitive head-to-tail addition of acetyl or substituted acetyl units indirectly derived from acetate. The mechanism is similar to that for fatty acid biosynthesis but without the intermediate reductive steps.

Sclerotium (plural: sclerotia) A firm, compact mass of hardened mycelium with no spores in or on it. The sclerotia of *Claviceps purpurea* contain ergot alkaloids.

Secondary metabolite A small molecule usually synthesized after active growth has ceased by pathways not part of primary metabolism. Many secondary metabolites have strong biological activity.

Defining Statement

Mycotoxins are low molecular weight natural products produced by molds that are toxic to vertebrates in low concentrations. In most cases, mycotoxins are of limited taxonomic distribution, that is, they are made by only a few species within certain fungal genera. Animals are exposed to mycotoxins through ingestion, inhalation, and/or skin contact. The ensuing diseases produced by mycotoxin exposure are called mycotoxicoses; the vast majority of characterized mycotoxicoses are due to dietary exposure. Many mycotoxins are potent in low doses, that is, quite small amounts of these compounds can represent significant health effects. Since filamentous fungi are common and opportunistic organisms, mycotoxins are widespread. These toxins contaminate foods and feeds across the globe and are of increasing concern as possible contaminants of indoor environments. Some mycotoxins have been implicated as chemical warfare agents. As with all toxins, the route of exposure (i.e., how the substance enters the animal body), the dose (how much of the substance is present), and the duration (the length of time the mycotoxin is present) interact to affect the severity of the outcome. Mycotoxins are implicated in certain cancers as well as many different disorders affecting the gastrointestinal, urogenital, vascular, renal, respiratory and nervous systems. Some mycotoxins act as immunosuppressants, thereby reducing resistance to infectious disease. It is estimated that 25% of the world's crops, including many basic foods, are contaminated by mycotoxin-producing fungi. Although as yet unproven, there also is increasing concern that mycotoxins may be implicated in the adverse health effects associated with exposure to mold growth in damp indoor environments.

There is an ongoing need to protect the health of humans and susceptible animals by limiting their exposure to mycotoxins. Despite many years of research and the introduction of good practices in the chain of food production, storage, and distribution, mycotoxins continue to be a global problem. Many countries regulate mycotoxin levels in foods and feeds because of their public

[☆]*Change History:* February 2015. JW Bennett and GG Moore updated the text and further readings to this entire article.

This article is an update of J.W. Bennett, M. Klich, *Mycotoxins, Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 559–565.

health significance and commercial impact. In recent years, certain internationally focused groups such as the Gates Foundation have increased support for research on mycotoxin control in Africa and other highly impacted parts of the world.

Poisons and Toxins

The vocabulary surrounding 'poison' and 'toxin' is not uniform. Some experts use the words synonymously, while others make a distinction. For example, some purists say poison describes any harmful substance, while toxins are a subset of poisons made by living systems. Many zoologists make a further distinction and limit the use of toxin to proteinaceous poisons such as snake venom. When used in adjective form, the distinctions blur. Both poisonous and toxic materials encompass all substances that can be injurious to living systems (e.g., the toxic mustard gases of chemical warfare and the poisonous darts of certain South American tribes). Both 'toxin' and 'poison' imply a concept of concentration – they must be present in sufficient quantity to cause damage, illness, or death.

The vocabulary used to describe the toxic metabolites of fungi is especially peculiar in that the toxic metabolites produced by macrofungi-like mushrooms and shelf fungi are usually called mushroom *poisons* while the toxic metabolites produced by microfungi (molds and mildews) are called *mycotoxins*. The technical name for mushroom poisoning is 'mycetismus' while the technical name for mycotoxin poisoning is 'mycotoxicosis'.

In general, mycotoxins are not proteinaceous but, rather, one of a huge array of low molecular weight natural products. They are categorized together simply because they all are produced by molds and are all toxic to vertebrates in low concentrations. In most cases, individual mycotoxins are made by only a few species or genera of filamentous fungi. For example, aflatoxin production is limited to a few species of the genus *Aspergillus* while the trichothecenes are mostly produced by species within the genus *Fusarium*. Like all secondary metabolites, mycotoxins share the enigmatic property of cellular dispensability meaning that mycotoxigenic species can regularly grow and thrive, at least in the laboratory, without producing toxic secondary metabolites.

A Primer in Toxicology

One of the most famous statements in toxicology, attributed to Paracelsus, states "Everything is poison, there is poison in everything. Only the dose makes a thing not a poison." This concept is often stated as an aphorism: The dose makes the poison. In mycotoxicology, as in other branches of toxicology, the degree of harm caused by a mycotoxin will depend not only on an interaction between the nature and concentration of the chemical compound, but also on the metabolic status of the target organism, the route of exposure, and the potential for metabolic detoxification. Animals vary widely in their responses to a given mycotoxin dose based on age, sex, nutritional and gestational status, as well as their ability to detoxify. In general, the greater the amount of toxin exposure, the more severe an effect it will have. Since some mycotoxins are far more biologically active than others, there is a different threshold level (the lowest concentration that produces a harmful effect) for each compound. Further complicating the picture is that the threshold level may vary among animal species and even among individuals within a species population. Often the young are more sensitive to mycotoxin exposure than adult animals. Characteristics such as diet, pregnancy, general state of health, and drug interactions also impact mycotoxin sensitivity. Finally, illnesses that involve organs for detoxification, such as hepatitis, can increase the sensitivity of an organism to toxin exposure. Repeated exposure to low quantities of a mycotoxin over long periods of time also may cause serious harm. Thus, in assessing the health burdens associated with mycotoxins, it is important to distinguish between acute and chronic conditions. Acute reactions occur shortly after exposure to a high concentration of a given mycotoxin. Chronic conditions follow long exposure to low doses. It is almost always easier to discern the connection between exposure and disease for acute conditions than for chronic ones, especially when the outcome of chronic exposure is something like a subtle change in reproductive behavior or fertility.

Unlike the environmental toxins, where the most common mode of entry is inhalation or dermal contact, the most common mode of entry for mycotoxins is inadvertent ingestion from a contaminated food supply. Many mycotoxins are tasteless, so consumers are unaware that they are ingesting contaminated food. Even when mold growth is apparent, starving people will resort to eating infected commodities because the alternative choice is no food at all. Historically, the first recognized human mycotoxicoses are associated with the ergot alkaloid made by fungi in the genus *Claviceps* that infect grains such as rye. These ergot compounds are found in distinctive morphological structures called sclerotia and have both vasoconstrictive and neurological effects. The famous hallucinogen LSD is a semisynthetic ergot derivative. Outbreaks of human ergotism have been documented since medieval times. In addition, the historical veterinary literature is littered with reports of ill-defined outbreaks of animal toxicity in cattle, horses, poultry, and swine associated with feeding with moldy grains or bedding with moldy straw.

A Bewildering Diversity of Substrates, Mycotoxin-Producing Fungi, and Physiological Effects

The scientific literature surrounding mycotoxins is enormous and is published in a variety of disciplines from chemistry and mycology to molecular biology and environmental toxicology. The emphasis in the veterinary literature is different from that in the literature of human biology, which in turn differs from studies in analytical chemistry, classical mycology, or molecular genetics. For more detailed treatments, the reader is referred to the list of references given at the end of this article.

Because of the opportunistic nature of fungi, there is almost no foodstuff that has not, at one time or another, been found to be contaminated with a mycotoxin. They have been reported on cereals, dried seafood products, fruits, legumes, nuts, oil seeds, and spices. When farm animals eat mycotoxin-contaminated food, derivative mycotoxin residues can be found in meat and milk. Thus, aflatoxin M₁, a biotransformation product of the mold product aflatoxin B₁, has been found in sources as diverse as ice cream, yogurt, and human breast milk.

The Food and Agriculture Organization of the United Nations (FAO) estimates that global foodstuff losses due to mycotoxins are in the range of 10⁹ tons per year. The incidence of contamination varies with crop, preharvest stress factors such as drought and insect damage, and weather at the time of harvest. Once harvested, almost all foods can become susceptible to mold contamination at some stage during transport, storage, and/or processing. Finally, mycotoxin contamination can occur in the home after cooking, especially when foods are not properly stored. This is a particular problem in underdeveloped regions of the world where refrigeration is lacking. Moisture is the single most important variable. Fungi need sufficient water and warmth in order to grow and synthesize secondary metabolites; therefore, harvested foodstuffs should be stored in cool and dry conditions.

Each mycotoxin group exerts its toxic effects by a different mechanism. For example, aflatoxins intercalate with DNA, fumonisin is an inhibitor of sphingolipid biosynthesis, and trichothecenes interfere with protein synthesis. For each mycotoxin, the symptoms induced will vary with the pharmacological action of the toxin, but will also depend on the target organism susceptibility and toxin concentration. The best-studied mycotoxins include aflatoxins, ergot alkaloids, fumonisins, ochratoxins, patulins, and the trichothecenes.

The disease states associated with mycotoxins are named rather haphazardly. Sometimes vague diagnoses such as 'aflatoxicosis', 'stachybotrycosis', or 'tremorgen intoxication' are given, and other times the pathologies are named after the general condition (e.g., liver cancer) or the specific symptom (e.g., convulsions). Some diseases, such as Balkan endemic nephropathy, have been attributed to mycotoxins based on correlative evidence, but this etiology was disproven. Balkan nephropathy is due to a plant toxin called aristolochic acid that sometimes contaminates bread. Finally, certain obscure diseases have been postulated to be mycotoxin-based without any concrete evidence. For example, Onyalai is a rather mysterious disease entity encountered in central southern Africa that has been attributed to fungal-contaminated millet, sorghum, and/or maize. Nevertheless, even for well-studied mycotoxins, exposure and occurrence data are limited, so it is possible that world health officials are underestimating the general toxicological burden posed by these natural products while simultaneously being too quick to attribute rare disease entities to them.

The major mycotoxins are listed in Table 1, categorized by the fungal genera producing them. Important genera of mycotoxin-producing fungi include *Alternaria*, *Aspergillus*, *Chaetomium*, *Claviceps*, *Fusarium*, *Myrothecium*, *Penicillium*, and *Stachybotrys* as well as their teleomorphs (i.e., sexual stages). Because mold taxonomy is a challenging scientific enterprise, the literature is filled with erroneous reports or misidentifications of mycotoxin-producing fungi. An excellent compendium that lists correct species identifications, and documents the more egregious cases of misidentification, was published by Frisvad and colleagues in 2007.

In summary, mycotoxins – collectively – are a worldwide problem, although individual mycotoxins are most likely to be encountered in specific habitats, on specific foodstuffs, and under specific weather conditions. In general, mycotoxin contamination is worst among agricultural commodities kept under poor storage conditions with high temperature and high humidity. Aflatoxin is usually considered the most important mycotoxin, not only because aflatoxins are potent in extremely low concentrations but also because the producing molds colonize such a wide range of substrates across an equally wide range of habitats. Most experts believe that aflatoxin is a major factor contributing to the high rates of liver cancer in some parts of Africa and Southeast Asia.

Related Topics in Mycotoxicology

Zearalenone, a *Fusarium* polyketide metabolite, deserves special attention. This compound, often classified as a mycotoxin, is also called F-2. Zearalenone resembles estradiol and binds to estrogen receptors in mammals where doses as low as 1 µg kg⁻¹ may create a detectable uterine response in female swine. On the other hand, the lethal dose of zearalenone in guinea pigs is 5000 mg kg⁻¹. Accordingly, while biologically potent, zearalenone is not toxic in the usual sense of the term. This compound is better classified as an endocrine disrupter than as a mycotoxin, but because of the pathological estrogenic syndrome it causes in swine, zearalenone traditionally has been lumped together with other veterinary problems caused by toxic fungal metabolites. Chemical derivatives of zearalenone have found application as growth promoters in cattle, especially in the United States; their use has been banned in the European Union.

In recent years, mycotoxins have been implicated in the cause of an ill-defined syndrome called 'sick building syndrome' or 'damp building syndrome'. In the United States, popular fear of 'toxic molds in the environment' has been fueled by a sensationalist press and through unscrupulous insurance claims. Although macrocyclic trichothecenes have been demonstrated in the sera of individuals who had been exposed to *Stachybotrys chartarum* in indoor environments there is only circumstantial evidence linking molds and mycotoxins and their myriad symptoms to sick building syndrome. Documented adverse health effects of molds in indoor environments are largely associated with allergies to fungal spores, asthma and upper respiratory irritation. A great deal more research is needed about the possible health implications of mold growth on damp building materials and whether or not mycotoxins are contributing to the symptomology associated with the adverse health effects associated with time spent in damp indoor environments.

Table 1 Examples of major mycotoxins

<i>Producing genus and name of compound</i>	<i>Toxicogenic effect</i>
<i>Alternaria</i> toxins	
Tenuazonic acid	Protein synthesis inhibitor
AA-toxins	Sphingolipid metabolism inhibitor
<i>Aspergillus</i> species	
Aflatoxins	Carcinogen, mutagen, teratogen
Cyclopiazonic acid ^a	Calcium transport disrupter
Gliotoxin	Immunosuppressant
Ochratoxin ^a	Nephrotoxin
Sterigmatocystin	Carcinogen, mutagen
Verruculogen	Tremorgen
<i>Claviceps</i> toxins	
Ergot alkaloids ^a	Vasoconstrictive agents, neurotoxins
Penitrem ^a	Neurotoxin
<i>Fusarium</i> toxins	
Butenolide	Fescue foot disease in cattle
Fumonisin	Sphingolipid metabolism inhibitor
Moniliformin	Chromosome damage, heart failure
Trichothecenes (over 200 have been identified)	Many suppress protein synthesis
Deoxynivalenol (n)	Emetic agent
Diacetoxyscirpenol	Hemorrhagic agent
Nivalenol	Hemotoxin
T-2	Immunosuppressant
<i>Penicillium</i> toxins	
Citreoviridin	Inhibitor of ATPase
Citrinin	Nephrotoxin, hepatotoxin, fetotoxin
Mycophenolic acid	Immunosuppressant
Patulin ^a	Immunosuppressant, neurotoxin
Penicillic acid	Nephrotoxin
Penitrem A	Tremorgenin
Rubratoxin	Hepatotoxin
Secalonic acid	Cleft palate induction in mice
Xanthomegnin	Hepatotoxin, nephrotoxin
<i>Stachybotrys</i> toxins	
Atranone	Inflammatory agent
Satratoxin	Protein synthesis inhibitor

^aAlso produced by other genera.

Finally, mycotoxins have also been implicated as chemical warfare agents. Their use in Yellow Rain during the Cambodian War has been largely discredited. However, there is strong evidence that Saddam Hussein stockpiled aflatoxin for use in missiles, even though aflatoxin is a poor agent for chemical warfare.

Biosynthesis, Molecular Biology, and Genomics

Fungi are known to be inventive chemists, so it is not surprising that mycotoxins encompass many chemically unrelated fungal metabolites that are synthesized by several different secondary metabolite biosynthetic pathways. Most known mycotoxins are polyketides, nonribosomal peptides, or derived from isoprene pathways. Often the chemical structures contain elaborate cyclic or branched cyclic architecture (Figures 1 and 2). Aflatoxin, alternariol, citreoviridin, citrinin, ochratoxin, patulin, penicillic acid, secalonic acid, sterigmatocystin, and xanthomegnin are all examples of polyketide mycotoxins. Gliotoxin is a nonribosomal peptide, while the penitrems and trichothecenes are isoprene-derived. Many mycotoxins; for example, cyclopiazonic acid, are formed from a combination of more than one pathway.

The biochemical, genetic and molecular characterization of mycotoxin biosynthesis has been an active field for basic research. In early research, the aflatoxin, sterigmatocystin, and trichothecene pathways were elucidated using isotopically labeled precursors, blocked mutants and gene cloning. The genes of the aflatoxin and sterigmatocystin pathways are chromosomally clustered ('linked'), allowing common regulatory elements to be shared. Gene clustering may influence gene expression and regulation through modulation of localized chromatin structure. In addition, recent advances in genomics have made it possible to detect the genetic signatures of polyketide synthases, nonribosomal peptides synthases, and other secondary metabolite-associated genes as

Figure 1 Chemical structures of aflatoxin B₁, citrinin, ergotamine, and fumonisin.

well as their associated gene clusters. Genomic, proteomic, and metabolomic advances have revolutionized the study of mycotoxins and other secondary metabolites. High throughput genomic technologies have increased our understanding of gene function, genetic regulation, signal transduction and the response of mycotoxigenic fungi to environmental stimuli. Nevertheless, these advances have not yet been translated into cognate advances in mycotoxin control.

Another important development in mycotoxin research involves the discovery of sexual stages in the life cycles of several fungi previously thought to reproduce only asexually (clonally). Additionally, genetic recombination within and among mycotoxigenic fungal species can result in the creation of novel chemotype profiles and inhibit their control. These discoveries open the way to conduct genetic research on gene regulation and to create recombinant strains that may be useful in mycotoxin control strategies.

Mycotoxin Detection, Prevention, and Regulation

The detection of mycotoxins is crucial for food safety and is of growing concern for air quality measurements in indoor environments. Regulatory limits, sometimes stated as a 'tolerable daily intake', are based on extrapolations from animal models and on human epidemiological data.

Several international agencies such as The European Union, the Institute of Public Health in Japan, and the U.S. Food and Drug Administration have set recommended guidelines, sample products for detection and measurement of mycotoxins, and currently maintain websites that are good sources for information on mycotoxins. The following are good mycotoxin resources: The Council for Agricultural Science and Technology, the American Oil Chemists Society Technical Committee on Mycotoxins, the International Union for Pure and Applied Chemistry (IUPAC) Section on Mycotoxins and Phycotoxins, and the U.S. Food and Drug Administration Committee on Additives and Contaminants.

A compendium summarizing international regulations on mycotoxins is available from the FAO. IUPAC has a Mycotoxin Working Group; publishes a newsletter; sponsors proficiency testing, collaborative trials, and workshops on quality assurance for mycotoxin testing laboratories; and posts regular listing of worldwide mycotoxin regulations. Most of these resources are easily accessed via the internet. In addition, print versions have been published such as *The World Mycotoxin Journal* which is available from Wageningen Academic Publishers in The Netherlands.

Mycotoxin analysis involves sampling, extraction, clean up and separation, detection, and quantitation. Sample preparation often remains a stumbling block because the methods used for the separation of toxins from the other compounds in the sample will depend on the nature of the sample as well as on the nature of the toxin. Thus, extracting and quantifying aflatoxin from corn is

Figure 2 Chemical structures of ochratoxin, T-2 toxin, deoxynivalenol, and satratoxin H.

different from the same analysis involving human blood. The time between sampling and analysis is also critical because samples held in environmental conditions conducive to mold growth could easily produce mycotoxins within 1–2 days of sampling. The major methods used for separation are high performance liquid chromatography and thin layer chromatography. A variety of immunological mycotoxin assay kits are available commercially.

The main challenge in mycotoxin control is prevention. If the global climate is indeed warming, then there is the potential for increased incidences of mycotoxin contamination in agricultural commodities through the combined stress to plant hosts and favorable conditions for fungal infection. Although it is not reasonable to expect a mycotoxin-free food supply, many practices in tillage, handling, and storage can minimize contamination. More importantly, a number of international agencies support the education of farmers, especially in the developing world. In the case of aflatoxin control, non-aflatoxigenic *Aspergillus flavus* strains have shown promise as biocontrol against infection and contamination by aflatoxigenic fungi.

Conclusion

Significant economic losses are associated with mycotoxins due to their impact on human health and animal productivity. Apart from the bacterial, protozoan, and viral agents that cause ‘food poisoning’, world health authorities consider mycotoxins to be the most important human chronic dietary risk factor, higher than food additives, pesticide residues, or synthetic contaminants. Mycotoxin effects may be exacerbated by poor nutrition and health, so their toll is heaviest in regions of the world where malnutrition is prevalent and where the inhabitants are immunocompromised. Their burden in animal husbandry is even greater than that in human health because mold-damaged foodstuffs are often diverted into animal feed. Chronic mycotoxin exposure in

animal feeds leads to reduced growth rates, lower feed efficiency, infertility, and a general lowering of productivity. Although most of the emphasis in mycotoxin research has been in agriculture and veterinary medicine, mycotoxins are of great importance to many other areas of basic and applied research, such as cancer toxicology, food science, evolutionary biology, fungal molecular biology, and organic chemistry.

Nanoarchaeota

Emily St. John and Anna-Louise Reysenbach, Portland State University, Portland, OR, United States

© 2019 Elsevier Inc. All rights reserved.

Diversity and Exploration of the Archaeal Domain

Karl Woese's 1977 discovery of the archaeal domain dramatically shifted and expanded our view of the universal tree of life. Prior to this discovery, the Archaea or "Archaeobacteria" were thought to represent divergent members of the Bacteria. However, Woese's 16S ribosomal RNA (rRNA) gene trees revealed that the Archaea were very unique on the molecular level, often more similar to their eukaryotic relatives than to the Bacteria. Because of the small number of cultivated archaeal lineages, the Archaea were thought to be exclusively extremophilic or methanogenic, limited to a few specific niches across the planet. The archaeal domain was initially divided into two main kingdoms, which are now called phyla: the thermophilic Crenarchaeota and the Euryarchaeota, comprised of methanogens, halophiles, thermophiles and sulfate reducers.

Exploration into the third domain of life quickly began to reveal the true extent of archaeal diversity, both on the phylogenetic and physiological level. A third archaeal phylum, the Korarchaeota, was discovered in the early 1990s based on 16S rRNA gene sequences. Like the Crenarchaeota, the Korarchaeota are a thermophilic lineage, and were detected in a geothermal spring in Yellowstone National Park (YNP). However, korarchaeotal 16S rRNA genes sequences branched deep within the archaeal tree of life, prior to the split between Euryarchaeota and Crenarchaeota. The Korarchaeota represented the first phylum-level division in the Archaea to be proposed without a single cultivated representative, setting a precedent for many later-described lineages. Around the same time period, archaeal 16S rRNA gene sequences from marine environments were also amplified and sequenced, and a cold-loving archaeal lineage was found associated with a marine sponge, revealing that the Archaea were not solely limited to methanogenic and extremophilic lifestyles. Hints regarding the physiology of these moderate archaeal lineages came from a fosmid clone obtained from a soil sample, which contained both archaeal rRNA and genes typically involved in ammonia oxidation. Shortly thereafter, ammonia oxidation was demonstrated in a cultivated isolate. Although initially identified as cold Crenarchaeota, these temperate taxa were found to be widely distributed in marine and terrestrial environments and were later proposed to represent a novel mesophilic phylum, the Thaumarchaeota. The unique ability of some Thaumarchaeota to oxidize ammonia suggested that Archaea may play major roles in global biogeochemical cycling that were previously overlooked.

Yet another archaeal phylum, the Nanoarchaeota, was proposed in the early 2000s, once again expanding our understanding of archaeal diversity and physiology. These ultra-small Archaea were first identified in anaerobic enrichment cultures, where they were seen attached to the outer surface of hyperthermophilic Crenarchaeota. Sequencing revealed that *Nanoarchaeum equitans*, the first identified nanoarchaeote, harbored a highly unique 16S rRNA gene. This gene could not be amplified using traditional archaeal 16S rRNA gene primers, explaining why previous diversity studies failed to detect the lineage. Direct cultivation studies showed that *N. equitans* required direct cell-to-cell contact with its crenarchaeotal host for survival, although the host did not need any nanoarchaeotes. Whole genome sequencing also revealed that *N. equitans* contained a small, reduced genome with few biosynthetic genes, consistent with its host-dependent lifestyle. The Nanoarchaeota-host system became the first described interspecies symbiosis between two members of the Archaea, once again demonstrating the diversity and functional flexibility of the archaeal domain.

Since the identification of these first archaeal phyla, metagenomic and single-cell sequencing techniques have revolutionized the study of microbiology, leading to the proposal of many new archaeal phyla and higher-order divisions. Today, the Archaea are understood to be ubiquitous, thriving in both extreme and temperate environments across the globe. Key lineages of abundant, widely distributed Archaea have been discovered in subsurface and aquatic environments, contributing significantly to biogeochemical cycling, while other lineages of divergent Archaea have provided insights into the relationship between the archaeal and eukaryotic domains. As genetic material has continued to increase, the archaeal tree of life has also undergone significant restructuring, with several higher-order groupings proposed as a means to categorize major archaeal phyla.

In the time since the discovery of the Nanoarchaeota, several other archaeal lineages with reduced genomes have been identified, largely by metagenomics and single-cell genome sequencing. These taxa have been grouped with the Nanoarchaeota to form the DPANN superphylum, based on their tendency to cluster together in phylogenetic analyses. The DPANN superphylum was originally named for five key lineages (the Diapherotrites, Parvarchaeota, Aenigmarchaeota, Nanohaloarchaeota, and Nanoarchaeota) but now includes several additional phylum-level designations. Although they harbor relatively small genomes and often

have small cell sizes, members of the DPANN are highly diverse, and DPANN sequences have been recovered from a wide range of environments, including hypersaline habitats, groundwater, alpine lakes and acid mine drainage. Although some Archaea in the DPANN superphylum are thought to be free-living, no organism from the group has been successfully isolated in axenic culture. Genomic evidence also suggests that particular DPANN lineages may rely on a host or partner for survival, like the Nanoarchaeota. *In situ* imaging and enrichment cultivation have revealed intimate associations between different members of the DPANN and Euryarchaeota, suggesting that interspecies dependence may be a hallmark of some taxa in this group.

Despite the recovery of many DPANN genome sequences, the placement of the entire superphylum in the archaeal tree of life, and the Nanoarchaeota in particular, remains unclear. It also continues to be debated whether or not the DPANN superphylum truly represents a monophyletic group. Nonetheless, the discovery of diverse DPANN taxa suggests that the host-dependent lifestyle of the Nanoarchaeota may be widely distributed across multiple archaeal lineages. As the first characterized symbiosis between two Archaea, the Nanoarchaeota and their hosts greatly expand our understanding of the nature and evolution of interspecies interaction in the third domain of life, and they may provide valuable insights into the adaptations that allow diverse, small archaeal lineages to thrive across the globe.

Global Distribution of Nanoarchaeotes

The first cultivated nanoarchaeote, *N. equitans*, was discovered in enrichment cultures from Kolbeinsey Ridge, a shallow marine hydrothermal vent site near the coast of Iceland. However, with the development of nanoarchaeote-specific primers, sequences related to *N. equitans* were soon identified in geothermal sites around the world, including hot springs in YNP, New Zealand, Chile, Kamchatka and central Asia (Fig. 1). 16S rRNA gene diversity studies also identified nanoarchaeote-like sequences in lower temperature environments, including hypersaline ponds and the photic zone of Yellowstone Lake. While it is possible that Nanoarchaeota survive in lower temperature environments, the sequences identified in the photic zone of Yellowstone Lake may also represent cells that have drifted away from geothermal vent sites on the lake floor. In either case, however, it appears that Nanoarchaeota predominantly inhabit high-temperature habitats. Nanoarchaeote genomic signatures have also been identified at deep-sea hydrothermal vent sites along the Eastern Lau Spreading Center, Mid-Atlantic Ridge, Guaymas Basin and East Pacific Rise. A 16S rRNA gene sequence study at East Pacific Rise demonstrated that Nanoarchaeota and their hosts may be among the first organisms to colonize young deep-sea hydrothermal vent deposits, suggesting that Nanoarchaeota-host pairings may play a key role in the ecology of high-temperature hydrothermal systems. This study also recovered nanoarchaeote sequences both in the presence and absence of *Ignicoccus*-like sequences, providing the first hint that nanoarchaeotes may associate with diverse hosts.

Fig. 1 Maximum-likelihood phylogenetic tree of nanoarchaeotal 16S rRNA gene sequences, inferred under the GTRGAMMA model. The tree was rooted with *Desulfurococcus mucosus* 07/1^T, *Staphylothermus marinus* F1^T and *Ignisphaera aggregans* AQ1.S1^T. Bootstrap support (based on 1000 replicate trees) is shown where 80% or greater. The scale bar indicates 0.01 nucleic acid substitutions per site. Nanoarchaeote sequences are colored based on geographical location.

Diversity Within Nanoarchaeote-Host Systems

Despite their broad distribution across geothermal environments, only three Nanoarchaeota-host systems have been successfully cultivated in the laboratory setting. Cultivated nanoarchaeotes vary in size, but they have consistently small cell diameters (~100–400 nm), and each nanoarchaeote relies on a distinct host from the Crenarchaeota (Table 1). The three cultivated nanoarchaeote-host pairings all appear to be specific, although the crenarchaeotal hosts are highly diverse.

N. equitans, the first described nanoarchaeote, associates with *Ignicoccus hospitalis*, a hyperthermophilic Crenarchaeota with a highly streamlined genome. *I. hospitalis* fixes carbon using the efficient dicarboxylate/4-hydroxybutyrate cycle and obtains energy via sulfur reduction. Members of the *Ignicoccus* are relatively unique among the Archaea due to the extensive double membrane surrounding their cells. *I. hospitalis* has a large periplasmic space between its inner and outer membrane, which often contains vesicles and/or protrusions. Energy generation in *I. hospitalis* takes place across the energized outer membrane, which houses an ATP synthase complex and enzymatic machinery needed to generate a proton gradient. This extensive endomembrane system likely has played a key role in the evolution of the *N. equitans*-*I. hospitalis* interaction.

A second and third cultivated nanoarchaeote-host system were isolated from geothermal springs in YNP and New Zealand. The YNP nanoarchaeote, *Candidatus* Nanopusillus acidilobi, was obtained from Cistern Spring, an acidic geothermal pool. *Cand. Nps. acidilobi* associates with the acidophilic lineage *Acidilobus* sp. 7A. Unlike autotrophic *I. hospitalis*, *Acidilobus* sp. 7A is a heterotroph that ferments protein- and carbohydrate-rich substrates. The New Zealand nanoarchaeote, *Candidatus* Nanoclepta minutus, was cultivated from a circum-neutral hot spring in New Zealand. *Cand. Ncl. minutus* lives on the surface of *Zestosphaera tikiterensis*, the first representative of a novel genus in the Crenarchaeota. *Z. tikiterensis* is also a heterotroph that degrades proteinaceous substrates and requires thiosulfate for growth. In contrast to *I. hospitalis*, neither of the cultivated terrestrial hosts have a double membrane system. Instead, both *Acidilobus* sp. 7A and *Z. tikiterensis* encode for an S-layer, a protein-based lattice that envelops the cell.

Several additional nanoarchaeote-host pairings have also been identified using single-cell genome sequences from hot springs in YNP. Because of the close relationship between the Nanoarchaeota and their hosts, single-cell genome sequencing techniques often recover both nanoarchaeotal and host DNA, providing a method of assessing host diversity. Putative nanoarchaeote hosts from YNP span several genera and include lineages related to the *Sulfolobales*, *Metallosphaera*, *Caldivirga*, *Thermocladium* and *Vulcanisaeta*. Despite this diverse array of hosts, however, single-cell amplified nanoarchaeotes show high 16S rRNA gene sequence similarity (>95%) to the cultivated lineage *Cand. Nps. acidilobi*, suggesting that YNP Nanoarchaeota may undergo frequent host-switching events. It is currently unclear what may be driving this rapid host diversification. However, both nanoarchaeote and host cell envelope structure may play a crucial role. An analysis of synonymous versus non-synonymous mutations in single-cell amplified YNP nanoarchaeotal genomes suggested that hypothetical cell-surface proteins in the Nanoarchaeota undergo rapid evolution, which may provide the novel mutations needed to facilitate new host associations. Additionally, several of the putative host lineages likely have S-layers, a similarity that may allow for more frequent host-switching events.

Although no Nanoarchaeota have been cultivated from deep submarine hydrothermal vent environments, three nanoarchaeotal metagenome-assembled genomes (MAGs) have been obtained from deep-sea hydrothermal vents sites across the world. However, without cultivation or single-cell sequencing approaches, it is nearly impossible to determine what host organism(s) associate with these Nanoarchaeota. No *Ignicoccus*-like bins were recovered from any of these deep-sea metagenomes, but one data set contained a bin closely related to the New Zealand host lineage *Zestosphaera*. This suggests that marine nanoarchaeotes may associate with multiple hosts, not just *I. hospitalis*, and some of these host organisms may resemble their terrestrial counterparts on the phylogenetic level.

Table 1 Various features of cultivated nanoarchaeota and their hosts

	<i>N. equitans</i>	<i>Cand. Nps. acidilobi</i>	<i>Cand. Ncl. minutus</i>
Location	Kolbeinsey Ridge	Cistern Spring, YNP	Cooking Pots, NZ
Geothermal feature	Shallow hydrothermal vent	Geothermal spring	Geothermal spring
Cultivation pH	5.5	3.6	6.0
Cultivation temperature (°C)	85–90	82	80–85
Host	<i>Ignicoccus hospitalis</i>	<i>Acidilobus</i> sp. 7A	<i>Zestosphaera tikiterensis</i>
Host family	Desulfurococcaceae	Acidilobaceae	Desulfurococcaceae
Host metabolism	Autotroph	Heterotroph	Heterotroph
Trans-spliced tRNA	+	–	–
Cis-spliced tRNA	+	+	+
RNase P	–	+	+
ATP synthase	P	–	–
RNase P	–	+	+
Split protein-coding genes	+	+	+
CRISPR-Cas cassette	+	–	+

Note: YNP, Yellowstone National Park; NZ, New Zealand; +, present; –, absent/not detected; P, partial.

Nanoarchaeote-Host Interaction Dynamics

Although all three cultivated nanoarchaeotes have an ectosymbiotic lifestyle, most of our understanding of Nanoarchaeota/host interactions comes from the *N. equitans*-*I. hospitalis* system, which has been studied for over 15 years and can be cultivated in large volumes using an anaerobic fermenter. Like all cultivated nanoarchaeotes, *N. equitans* largely relies on its host for the production of metabolic building blocks. Labelling studies have demonstrated that *I. hospitalis*-synthesized lipids and amino acids are transferred to *N. equitans*. Likely, this exchange takes place via a pore-like structure that connects *I. hospitalis* and *N. equitans*, where the cytoplasm of host and nanoarchaeote appear to meet. While studies of the *N. equitans*-*I. hospitalis* system are much more extensive, electron microscopy has also revealed a similar pore-type formation between terrestrial nanoarchaeote *Cand. Ncl. minutus* and its host and membrane stretching at the attachment site of *Cand. Nps. acidilobi* and *Acidilobus* sp. 7A. Due to the differences in host cell envelope, the mechanism of association in these terrestrial nanoarchaeote-host systems may be very different compared to that of *N. equitans* and *I. hospitalis*. Nevertheless, imaging studies suggest an equally intimate attachment between all cultivated Nanoarchaeota, which may involve cytoplasmic bridging.

In the laboratory setting, different nanoarchaeotes appear to have variable effects on their respective hosts. Although *N. equitans* does not significantly affect the growth rate or final population of *I. hospitalis* cells, the growth curves of the two organisms are not synchronized during cultivation. *N. equitans* cells continue dividing exponentially after *I. hospitalis* enters stationary phase, and nanoarchaeotes may eventually outnumber *I. hospitalis* cells by a factor of ten. Also, infection with nanoarchaeotes can hamper or even halt the ability of *I. hospitalis* to divide, indicating a high cost for individual host cells. In contrast, the growth of the YNP nanoarchaeote *Cand. Nps. acidilobi* is synchronized closely with that of its host, *Acidilobus* sp. 7A, with *Acidilobus* cells consistently outnumbering nanoarchaeotes. Growth profiles of pure culture and co-cultured *Acidilobus* sp. 7A also show no appreciable difference. Overall, this may suggest that *Cand. Nps. acidilobi* is less damaging to host growth and survival than *N. equitans*. In the *Cand. Ncl. minutus*-*Z. tikiensis* system, direct counts of host cells and qPCR-derived counts of nanoarchaeotes also appear to be synchronous, pointing to a system more similar to the YNP nanoarchaeote/host symbiosis. Notably, *Cand. Ncl. minutus* is able to grow to much higher densities in complex enrichment cultures compared to co-culture with *Z. tikiensis*. Although *Z. tikiensis* functions as the obligate and primary host for *Cand. Ncl. minutus*, it is possible that other lineages provide nutrients or small molecules that encourage nanoarchaeote growth. To date, all cultivated nanoarchaeote-host pairings appear to be specific, and most cross-infection studies have been largely unsuccessful. Although rare host-switching events have been observed in the laboratory, none of these novel Nanoarchaeota pairings have been maintained. However, this does not rule out the possibility that nanoarchaeotes engage in a variety of interactions with diverse organisms in their natural geothermal habitats, all while maintaining their obligate host associations.

Proteomic data comparing pure *I. hospitalis* cultures and *N. equitans*-*I. hospitalis* co-cultures has also revealed some of the effects of Nanoarchaeota association on the host. *I. hospitalis* cells show differential changes in transcriptional regulator expression when cultivated with *N. equitans*, suggesting that nanoarchaeote association causes highly controlled, specific changes within the host. Over time, co-cultivation with *N. equitans* also causes increases in expression of host carbon fixation and energy generation genes, likely in response to the increased metabolic demands from the nanoarchaeotes. Stress proteins are shown to be highly expressed in the *I. hospitalis* proteome, although the organism does not appear to mount a significant defensive response to nanoarchaeotal infection. High levels of stress proteins were also detected in the proteome of YNP host *Acidilobus* sp. 7A when co-cultivated with its Nanoarchaeota. However, because no proteomic data from pure *Acidilobus* sp. 7A cultures is available, it is unclear whether or not these proteins are expressed in reaction to nanoarchaeotal infection, or if they represent a constitutive response to environmental stressors. In the future, comparative proteomic studies such as those performed on the *N. equitans*-*I. hospitalis* system will be pivotal in determining whether or not terrestrial hosts react to their respective nanoarchaeotes in a similar manner.

Shared Genomic Features of Cultivated Nanoarchaeotes

Like many obligate symbionts and parasites, cultivated Nanoarchaeota have reduced genomes, ranging in size from 0.491 (*N. equitans*) to 0.606 Mbp (*Cand. Nps. acidilobi*). Although described Nanoarchaeota have a fairly extensive set of genes used in cell replication, RNA transcription and protein translation, they have lost most biosynthetic capabilities. Without these core functions, Nanoarchaeota rely on host-produced cofactors, nucleotides, lipids and amino acids. Each of the three genomes also encode split protein-coding genes, which are in multiple open reading frames spread across the genome. At least some of these split genes likely maintain their functionality, as demonstrated for the split alanyl-tRNA synthase in *N. equitans*. Although the three cultivated Nanoarchaeota share a common set of split protein-coding genes, several unique split genes are also scattered across the three genomes. Some of these split genes have also been recovered in single-cell nanoarchaeotal genomes from YNP and Nanoarchaeota MAGs from deep-sea hydrothermal vents. These patterns of distribution suggest that the last common ancestor of described nanoarchaeotal lineages already had split protein-coding genes and that genomic fragmentation has continued to occur after these taxa diverged. Because of the fast-evolving nature of the reduced and fragmented Nanoarchaeota genomes, the positioning of the nanoarchaeotal lineage and the DPANN group in the archaeal tree remains unclear. However, split protein-coding genes in the Nanoarchaeota are typically seen as a derived feature, resulting from genome degradation due to host association.

In addition to their lack of biosynthetic genes, cultivated Nanoarchaeota do not have any apparent means of ATP production. Although *N. equitans* encodes a partial ATP synthase, the complex is quite divergent and cannot undergo conformational changes, which are necessary for enzyme functionality. Additionally, no ATP synthase complex genes could be identified in the genomes of

Cand. Nps. acidilobi or *Cand. Ncl. minutus*, suggesting this method of ATP generation is not functional across nanoarchaeotal lineages. The glycolysis pathway, which can produce minimal ATP through substrate-level phosphorylation, is also not complete in any of the three cultivated nanoarchaeotal genomes. One deep-sea Nanoarchaeota MAG contains genes for the pentose biphosphate pathway, which may provide a way for the nanoarchaeote to produce minimal ATP after circumventing the early steps of glycolysis. However, this pathway is thus far restricted to one nanoarchaeotal MAG, and it is unknown whether or not these enzymes are functional *in vivo*. Without a widely-distributed means of synthesizing ATP, most Nanoarchaeota likely rely on their hosts for ATP production. Co-cultures of *N. equitans* and *I. hospitalis* have been shown to contain less ATP than pure *I. hospitalis* cultures, supporting this hypothesis and suggesting that nanoarchaeotes are utilizing host-produced ATP to fuel their own metabolic processes. Complete and partial dependence on host ATP has been identified previously in obligate intracellular symbionts and parasites, including pathogenic *Chlamydia* and the insect symbiont *Cardinium*. Both of these intracellular organisms contain ATP transporters to import host-produced ATP across the membrane, which have not been identified in the Nanoarchaeota. However, nanoarchaeotes may siphon ATP directly away from their hosts through the pore-like bridge connecting the two organisms.

Despite their small size and highly reduced gene content, the three cultivated Nanoarchaeota have efficient genomes with high coding density. Compared to obligate intracellular Bacteria, the nanoarchaeotes have maintained a higher level of genomic integrity and avoided extensive genome collapse. The three cultivated Nanoarchaeota have also retained their DNA repair mechanisms, which are often lost in endosymbiotic lineages, allowing them to avoid a buildup of deleterious mutations. Also, Nanoarchaeota have the added advantage of exposure to the outside environment, which provides them with avenues for horizontal gene transfer (HGT) from viruses and neighboring cells. Based on genomic analysis of the *N. equitans*-*I. hospitalis* system, HGT also appears to occur between the host and nanoarchaeotal symbiont, which may help Nanoarchaeota compensate for gene loss events. The differences between nanoarchaeotal genomes and those of obligate endosymbiotic Bacteria may point to the different selection pressures affecting genome size and structure in these diverse environments. In the case of endosymbionts, isolation within the host typically leads to massive gene loss and degradation, with few mechanisms for recovering lost functions. However, genome reduction in the Nanoarchaeota may be a product of both host dependence and the high-temperature geothermal habitat, which tends to select for smaller cell volumes, streamlined genomes and shorter gene variants, all while avoiding the extreme isolation of the intracellular environment.

Unique Features of Various Nanoarchaeotes

Although all cultivated Nanoarchaeota share a similar ectosymbiotic lifestyle, their genomes harbor some key differences. *N. equitans* has the smallest genome of any cultivated Nanoarchaeota and shows more extensive gene loss and reduction compared to its terrestrial relatives, which is especially evident in its RNA systems. *N. equitans* is lacking the RNase P complex, previously thought to be ubiquitous across all life. RNase P performs a crucial step in the generation of mature RNA molecules by trimming the 5' leader sequence from precursor tRNAs. However, *N. equitans* can function without RNase P due to its shifted tRNA promoter regions, which allow precursor tRNAs to be transcribed without a leader sequence. Both cultivated terrestrial Nanoarchaeota appear to retain the enzyme, and RNase P protein subunits have been identified in multiple nanoarchaeotal MAGs from marine hydrothermal vents, suggesting that RNase P is typically maintained across nanoarchaeotal lineages. The loss of RNase P in *N. equitans* likely reflects the high level of genomic reduction found in this particular Nanoarchaeota.

Trans-encoded tRNA genes in the *N. equitans* genome also support a scenario of extensive genome rearrangement. These split tRNA genes are encoded in multiple pieces, which are fused into functional tRNAs after transcription using a nanoarchaeotal splicing endonuclease. Since their discovery in *N. equitans*, *trans*-spliced tRNA genes have also been identified in several lineages of free-living Crenarchaeota. Potentially, these split tRNA genes represent a defense mechanism used to avoid integration of viral DNA, which targets conserved tRNA gene sequences, or they may be the product of previous insertion events. Alternately, it has also been proposed that these *trans*-encoded tRNA genes represent an ancestral gene form, which carries implications for the evolutionary history of extant tRNA genes. To date, no split tRNA genes have been identified in any nanoarchaeotal lineage outside of *N. equitans*.

Genomic evidence suggests that diverse Nanoarchaeota interact with the abundant viral populations found in geothermal environments. CRISPR-Cas cassettes have been identified in *N. equitans* and *Cand. Ncl. minutus*, and *cas* genes have been discovered in deep-sea nanoarchaeotal MAGs. Integrated prophage DNA has also been found in single-cell amplified nanoarchaeotal genomes from YNP. However, no CRISPR-Cas regions were detected in YNP Nanoarchaeota genomes, suggesting that defense mechanisms against viral infection may not be distributed across all nanoarchaeotal lineages. While viruses may pose a threat to nanoarchaeotal cells, they may also provide a reservoir of genetic material which could serve to replace lost gene functions through HGT.

Compared to *N. equitans*, both terrestrial nanoarchaeotes have somewhat expanded genomes, and both contain genes that are lacking in their marine relative. Most notably, *Cand. Nps. acidilobi* and *Cand. Ncl. minutus* both encode genes for the archaeal flagellum, which are expressed in the proteome of *Cand. Nps. acidilobi* and are visible by electron microscopy in *Cand. Ncl. minutus*. Unlike most Archaea, however, the archaeal flagellar genes are not encoded in an operon, once again pointing to patterns of genome reshuffling in the Nanoarchaeota. Currently, the function of the archaeal flagella is unclear, especially given the apparent inability of cultivated nanoarchaeotes to produce ATP needed to fuel motility. However, it is possible that the Nanoarchaeota may use their archaeal flagella only when attached to their hosts, fueling motility with host-produced ATP. Alternately, the archaeal flagella may have a function in the association between Nanoarchaeota and their hosts. Both terrestrial nanoarchaeotes also encode genes for the gluconeogenic pathway, which are highly expressed in the *Cand. Nps. acidilobi*

proteome. Likely, these enzymes aid in the production of sugars for cell-surface glycosylation. This process may play a key role in the Nanoarchaeota-host association, potentially facilitating the wide diversity of nanoarchaeote-host pairings identified in YNP hot springs. Although archaeal flagella and gluconeogenic genes were not detected in the genome of *N. equitans*, their distribution does not appear to be governed by habitat type alone. Marker genes for gluconeogenesis and archaeal flagella were also identified in nanoarchaeotal MAGs from geographically distant deep-sea hydrothermal vents, suggesting these features may be widely distributed across the Nanoarchaeota. Once again, this pattern suggests that *N. equitans* represents a more highly reduced lineage compared to other described nanoarchaeotes. However, as more Nanoarchaeota-host pairings are identified, additional eco-physiological patterns may emerge that are not yet apparent.

Conclusions

The Nanoarchaeota represent a diverse, widely distributed lineage thriving in geothermal environments around the world. The highly specialized host-dependent lifestyle of the nanoarchaeotes provides unique insights into interspecies relationships across the Archaea. However, the three described Nanoarchaeota-host systems defy easy classification. Although the nanoarchaeotes initially resemble parasites, relying on their hosts for the majority of metabolic products, they cause fewer detrimental effects to the host than expected. Marine and terrestrial Nanoarchaeota also appear to interact with their hosts in different ways, as evidenced by unique growth patterns during cultivation. To date, no positive benefits of Nanoarchaeota infection have been demonstrated in the laboratory setting, although nanoarchaeotal association may provide yet unknown benefits to hosts in their diverse natural communities. Further cultivation and genome sequencing will be crucial to understanding the intricacies of the Nanoarchaeota-host interaction, and the role this symbiotic system plays in the ecology of hot springs and deep-sea hydrothermal vents.

Nitrogen Assimilation in Bacteria

Antonia Herrero and Enrique Flores, Consejo Superior de Investigaciones Científicas and Universidad de Sevilla, Seville, Spain

Introduction

Nitrogen is a main component of living organisms, accounting for 10%–15% of the dry weight of bacteria, which represents $\frac{1}{4}$ of their carbon contents. In living matter, nitrogen is present in nucleic acids and proteins, the defining molecules of cells, and in bacteria it is also present in cell walls. Moreover, besides its importance for the organism that conducts the process, biological nitrogen assimilation is a crucial part of the global carbon and nitrogen cycles, and has thus a major impact on climate and planetary composition at global scales.

Nitrogen is found in different molecular forms in all natural environments in our planet, and these forms are interconverted with a massive participation of microorganisms (Fig. 1). In soils, nitrogen is found in organic forms, mainly derived from animal waste and organic matter decomposition, or inorganic compounds, mainly ammonium, although other compounds such as nitrates, nitrites and nitrogenous oxides are also present. The relative composition of nitrogen in land depends very much on the particular environment. In fresh waters the content of nitrogenous compounds is also variable and could be related to that of in-shore lands. In oceans, nitrate, ammonium and urea can reach micromolar concentrations. The main component of the Earth's atmosphere is N_2 ($N \equiv N$, 78%), which to a large extent is of biological origin.

The bulk of the biological transformations of nitrogenous compounds in land and water environments take place through the processes of: ammonification, carried out by bacteria and fungi and whereby organic nitrogen is transformed into ammonium; bacterial nitrification, which involves the conversion of ammonium into nitrites and nitrates; nitrate and nitrite assimilation, the intracellular conversion by plants and microorganisms of nitrate and nitrite into ammonium; and the anaerobic processes of bacterial denitrification and anammox, which involves the conversion of nitrate or ammonium, respectively, into N_2 gas, which is liberated to the atmosphere (Fig. 1). Although some transformation of atmospheric N_2 into nitric oxides and nitrate takes place through natural atmospheric phenomena such as lightning and volcanic activity, and into ammonium by industrial processes to produce fertilizers, the main pathway of transformation of N_2 nitrogen is through biological N_2 fixation. This process, which is exclusively conducted by prokaryotes, either free-living or in symbiosis with eukaryotes, represents the main way to introduce N into the biologically utilizable pool (Fig. 1). Thus, it is of primordial importance to maintain the global ecological stasis.

The oxidative processes of nitrification (by nitrifying bacteria) or anammox and the reduction of nitrate by denitrifying bacteria are used for the production of reductant and energy, while the dissimilatory reduction of nitrate and nitrite can be used to generate energy or serve detoxification purposes (e.g., to eliminate excess of reductant or nitrite). In contrast, the assimilatory reduction of nitrate, nitrite and N_2 is, together with the direct incorporation of ammonium or of some forms of organic N, directed to building organic matter for growth, often in an energy-dependent manner (Fig. 1). In the following sections, we describe these assimilatory processes (Fig. 2) and their regulatory control. Given their central nature, we first cover ammonium assimilation and its regulation. We then study the assimilation of alternative N sources and their specific regulatory mechanisms, and conclude emphasizing the global systems of N control.

Fig. 1 Main paths of nitrogen cycling in Nature. The global processes accounting for the bulk of transformations of nitrogen forms taking place in natural habitats are represented. Except for nitrate/nitrite assimilation, in which plants and algae have an important contribution, and ammonification, in which fungi have a role, all others are carried out by bacteria and archaea.

Fig. 2 Core and some peripheral nitrogen assimilation pathways in bacteria. The assimilation of ammonium through the GS-GOGAT cycle is at the core of nitrogen assimilation in bacteria. Ammonium can be taken up from the medium or derived from inorganic sources of nitrogen including nitrogen gas (dinitrogen), nitrate and nitrite, as shown in the upper part of the scheme. Nitrogen can be obtained also from organic nitrogen sources including the core amino acids glutamine and glutamate. Other organic nitrogen sources, shown here as examples, include urea, arginine, asparagine, aspartate, histidine and the xenobiotics atrazine and cyanuric acid. Amino acids that serve as excellent nitrogen sources can be catabolized producing glutamate and ammonium; atrazine and urea serve as nitrogen sources because they can be catabolized releasing abundant ammonium. The family to which each represented transporter belongs is indicated (for further information on transporter families, see the Transporter Classification Database at <http://www.tcd.org>). (Transporters for glutamate and glutamine are not depicted in the figure.) The names of some enzymes or gene products that participate in the catabolism of the indicated nitrogen sources (amino acids in three letter code) are shown: AnsA, periplasmic asparaginase (*B. subtilis*); AnsB, aspartase (*B. subtilis*); AspC, aspartate aminotransferase; Atz, atrazine degrading proteins; GS, glutamine synthetase; GOGAT, glutamate synthase; Hut, histidine degrading proteins; Nar, nitrate reductase; NifHDK, nitrogenase complex; Nir, nitrite reductase; RocF, arginase (*B. subtilis*), also known as ArcA (*Agrobacterium tumefaciens*); Ure, urease. The dashed arrow in arginine catabolism denotes two different sub-pathways described in the text within pathway 1 and pathway 2 ([N], nitrogen conserved as glutamate in 1 or as ammonium in 2). Only substrates/products relevant for our discussion are indicated, and stoichiometry of the reactions is not specified.

Ammonium Assimilation

Ammonium Uptake

The ammonium ion (NH_4^+) is a key compound in the assimilation of nitrogen in numerous biological systems because it is the inorganic form of nitrogen that is incorporated into carbon skeletons. Ammonium present in the environment can be assimilated by many bacteria, yeast, fungi, algae, and plants. Ammonium solutions always contain ammonia (NH_3) (the pK_a of ammonium/ammonia is 9.25), which can diffuse through biological membranes. Diffusion of ammonia followed by trapping of intracellular ammonium by glutamine synthetase can represent a significant process for nitrogen acquisition, especially in organisms such as some bacteria that can grow in alkaline media. This process would be less important in fungi that grow in acidic media. However, in numerous organisms there is evidence for the presence of ammonium transport systems that can be conveniently probed with ^{14}C -labeled methylammonium (the pK_a of methylammonium/methylamine is 10.65). Genes encoding ammonium/methylammonium permeases were first identified in *Saccharomyces cerevisiae* (MEP) and *Arabidopsis thaliana* (AMT1). Of note, the Rhesus proteins in chordates are homologues of the ammonium transporters. Genes coding for proteins similar to MEP- and AMT1-encoded proteins are ubiquitous in bacterial genomes, where they are denoted *amtB* or a variation thereof. For instance, a gene that has been denoted *amt1* is widespread in cyanobacteria.

The Amt proteins

Bacterial Amt proteins contain 400–500-amino acid residues. They are integral membrane proteins that normally have 12 transmembrane segments. The N-terminal transmembrane segment is frequently part of a signal sequence that is removed after integration of the protein into the membrane. The crystal structures of the AmtB proteins from *Escherichia coli* and the euryarchaeon *Archaeoglobus fulgidus* are available, showing that AmtB forms trimers in which each monomer provides a hydrophobic pore to accommodate and conduct the substrate. Although the nature of the transferred substrate (NH_4^+ or NH_3) has been debated, recent work supports early conclusions based on physiological studies that the transferred substrate is the ammonium ion, although the mechanism of transport could involve a deprotonation step and parallel transfer of a proton. The net result of transport is concentration of ammonium inside the cells dependent on the membrane potential (negative inside the bacterial cells), and incorporation of ammonium into glutamine catalyzed by glutamine synthetase (GS). This has been clearly shown also in studies using [^{14}C]methylammonium as a substrate, in which intracellularly accumulated [^{14}C]methylammonium and [^{14}C]methylglutamine are detected.

Bacterial Amt proteins have a very high affinity for ammonium (K_s values below micromolar), and the expression of *amt* genes is commonly repressed by high concentrations of ammonium in a process that involves the global nitrogen regulatory system, e.g., Ntr in the enterobacteria or NtcA in cyanobacteria (see Section “Nitrogen Control”). Indeed, the Amt proteins are not needed for ammonium assimilation when ammonium is provided at high levels (e.g., in the millimolar range at a neutral pH), as demonstrated by the ability of *amt* knock-out mutants to grow using ammonium as a nitrogen source.

Regulation of *amtB*

The *amtB* gene is frequently clustered together with *glnK*, which encodes a P_{II} -like protein. As described in the section on N control, P_{II} proteins are sensors of the nitrogen status of the cell. In enterobacteria, P_{II} proteins are modified by uridylation under low-nitrogen conditions. In the presence of a non-limiting ammonium concentration, the GlnK trimer is deuridylylated and binds the AmtB trimer, inhibiting ammonium transport (Fig. 3).

In conclusion, the Amt proteins function to scavenge ammonium when this substrate is found at low extracellular concentrations. Because of the paired presence of ammonium and diffusible ammonia in solution (respective concentrations depending on pH), when the concentration of the $\text{NH}_4^+/\text{NH}_3$ pair is too high, the cells respond repressing *amt* gene expression and frequently also blocking AmtB activity. These responses could impede the operation of a futile cycle in which the ammonium concentrated within the cells leaks out due to unavoidable ammonia diffusion.

Incorporation of Intracellular Ammonium Into Carbon Skeletons

We will show throughout this article that all N sources eventually yield intracellular ammonium. This is not surprising, since N in NH_4^+ is at the same oxidation state as the organic N present in biological molecules. Intracellular ammonium, either coming from NH_4^+ uptake or from the assimilation of alternative N sources, is incorporated into C skeletons by reaction with organic acids to yield amino acids. 2-oxoglutarate is the preferred ammonium acceptor, to yield glutamate and glutamine. Glutamate and glutamine provide the N for all the other amino acids, while glutamine provides N for nucleotide and amino sugar biosynthesis.

Enzymatic routes

Glutamate and glutamine are the main entry points of N to the organic pool in bacteria. Glutamine synthetases (GS) catalyze the amidation of glutamate to yield glutamine at the expense of one molecule of ATP. A second enzyme, glutamate synthase (GOGAT), produces two molecules of glutamate from one of 2-oxoglutarate and one of glutamine, consuming two reducing equivalents. Through the concerted action of the GS/GOGAT two-enzyme system (Fig. 2), ammonium is incorporated into 2-oxoglutarate with high affinity, but one ATP is consumed per glutamate formed. A third enzyme, glutamate dehydrogenase (GDH) can catalyze the reductive amination of 2-oxoglutarate to yield glutamate using a reduced pyridine nucleotide, but the reaction equilibrium is

Fig. 3 Structure and scheme of AmtB and its inhibition by GlnK. Structure of the AmtB trimer (A) and the AmtB-GlnK complex (B) from *Escherichia coli* viewed in the membrane plane. Structure references are 1UTG for AmtB and 2NS1 for AmtB-GlnK. (C) Schematic of the blocking of AmtB (inserted in the cytoplasmic membrane) by GlnK that takes place when the ammonium concentration is high, which determines a low C-to-N balance that results in deuridylylation of GlnK as explained in the text.

heavily displaced in the opposite direction, and GDHs are usually catabolic. In enterobacteria and in many other bacteria, both systems coexist. Other bacteria can lack GDH or, more rarely, GOGAT. In enterobacteria, GS is a dodecamer of identical subunits, each with an active site. In other bacteria, GS can be much simpler. Still other bacteria contain more than one type of GS, which can increase the flexibility of their N assimilation pathways. In enterobacteria, GOGAT is a heterodimeric, iron-sulfur flavoprotein that uses NADPH. In other bacteria, NADH or even ferredoxin are preferred over NADPH, and it is not uncommon for bacteria to harbor more than one type of GOGAT.

Other, minor, ways of ammonium incorporation into organic skeletons exist, such as NAD⁺ synthase or the amidation of aspartate catalyzed by asparagine synthetase, but one of them in particular, the synthesis of alanine from pyruvate and ammonium, catalyzed by alanine dehydrogenase, appears to be important in diazotrophic legume bacteroids of some rhizobia, both as a sink of fixed ammonium and as a N-delivery molecule to the plant.
